Conservation and measurement of area have been assessed by a variety of techniques. In one version (*ibid.*, Chap. 11) the child was presented with two identical cardboard rectangles, each made up of six detachable squares, and was shown that the same number of tiny wooden cubes exactly covered each rectangle. After a square had been detached from one of the rectangles and reattached elsewhere on the same rectangle, the child was asked if the set of cubes would still exactly and completely cover it, if there was still the "same amount of room" on the two rectangles, or similar questions designed to tune S in to area comparisons. It is abundantly clear from this and related investigations that young children fail to conserve area in the face of area-irrelevant transformations, again perhaps due to the absence of an atomistic, unit-parts view of surfaces, wherein whole areas are seen as composed of little part areas. As indicated in the previous section, Piaget has also done extensive research on three-dimensional conservation and measurement (i.e., conservation of volume).

Other Studies of Children's Spatial Concepts There are a number of subsequent investigations that have made use of Piaget's testing procedures (or variations thereof) in this developmental area. Three are "omnibus" replication studies, employing a whole battery of Piaget's tasks for the express purpose of checking his results (Dodwell, 1963, Lovell, 1959, Lovell, Healey, and Rowland, 1962). More focus on one or a few of his procedures, for replication or other purposes (e.g., Beilin and Franklin, 1962, Brame, 1959, Charlesworth, 1962, Peel, 1959, Pratoomraj and Johnson, 1966, Rivoire, 1962, and a number of training studies, such as that by Smedslund, 1963b, cited above).

As always, it is very difficult to summarize in a few sentences the results of such a heterogeneous body of research. Generally, these investigators seem to find roughly the same varieties of age-related immature, transitional, and mature cognitive responses that Piaget found. Quite often, however, they report differences in major and minor detail in mean ages of acquisition, ease of response classification, observed frequency of response types, intertask and intrachild inconsistencies which Piaget would not have led us to expect, and the like. As an example of this last, Beilin and Franklin (1962) found that conservation and measurement of length is definitely achieved earlier than the corresponding operations in the case of area, whereas Piaget, Inhelder, and Szeminska (1960, pp. 285–300) had believed them to be developmentally synchronous. Several studies lend at least qualified support to Piaget's hypothesis that topological properties are mastered earlier than projective and Euclidean ones (Dodwell, 1963, Lovell, 1959, Peel, 1959, Rivoire, 1962). However, the present writer believes that much more careful, parametric experimentation will be needed before the validity—and certainly the generality—of this particular developmental sequence is firmly established.

Several studies extend, supplement, or modify Piaget's research and theory in the domain of spatial representation. Vinh Bang (1965a, 1965b) and Lunzer (1965a) have both tested children's conservation-nonconservation judgments regarding bounded surfaces that are made to vary in shape. In some conditions, the perimeter is kept constant under

the shape transformation with the area changing, in others, the perimeter varies while the area is kept the same. True to type, younger children tend to conserve neither area nor perimeter in the face of these perceived changes. The interesting finding, however, was that many older (concrete-operational) children systematically asserted the continued invariance of *both* perimeter and area (wrongly so for one or the other, of course, depending upon the experimental condition)—a kind of overgeneralization of the conservation strategy. Vinh Bang's interpretation of this finding seems a reasonable one: "Once the concept of conservation is acquired, the child of 8-9 years thinks that invariance in one domain implies invariance in another, especially when the domains are related, as in the case of a perimeter and the area it generates" (1965b, p. 58). The aforementioned paper by Lunzer (1965) also makes the intriguing suggestion that the child may develop an earlier and a later operational conception of length, closely kin to the previously made distinction between "interior" and "occupied" volume (Piaget, Inhelder, and Szeminska, 1960, pp. 374-376). For a commentary on these and other recent Genevan studies on spatial concepts, see Piaget (1964b).

Middle childhood seems to be the favored epoch for the attainment not only of "conservation" (and occasionally "overconservation," so it now appears) but also of something which Beilin (1964, 1969) describes as "quasiconservation." Imagine that the child is shown the two identical cardboard rectangles used in the area conservation task described earlier, but *after*, rather than *before*, one of the six detachable squares has been removed from its original locus and reattached in a different place on the same rectangle. We then ask him if the two pieces of cardboard have the same area (not if they *still* have the same area, as in the ordinary conservation procedure, because he of course had *not* seen them in their initial, perceptually identical state). Although the two cardboards may not appear equal in area under these circumstances, it is possible to infer that they are, either by mentally relocating the itinerant square at its original position to reconstitute an intact rectangle (a "translocative" solution), or by simply counting the squares in each figure (an "iterative" solution). Such is

the essence of Beilin's area quasiconservation task. His data suggest that it tends to be mastered at a later age than is the corresponding conservation task. Beilin's (1969) explanation for this age difference is that quasiconservation inferences require more cognitive initiative on S's part, since there has been no perceived transformation from initial identity that might suggest to the child the nature of the problem and of its solution (e.g., the inverse operation of translocation).

Recent work by Braine and Shanks (1965a, 1965b) on children's reactions to illusory size and shape changes has led to an important hypothesis regarding the nature and origin of conservation. Their data indicate that it is not until about age 5 that children become capable of distinguishing between real and phenomenal properties of objects, for example, the recognition that one object may *look* (phenomenal) bigger than another and yet not *really be* (real) bigger. Braine and Shanks propose that the acquisition of the real-phenomenal distinction is a necessary precondition for conservation and may, for certain conservations tested for under certain task conditions, also prove to be a sufficient one. Given the structure of the conservation task, it is hard to imagine how at least the initial, necessary-condition part of this proposal could be wrong. Other relevant investigations in the area of spatial concept development are those by Drake (cited in Bruner, Olver, and Greenfield, 1966), Huttenlocher (1967), Lord (1941), Meyer (1940), and Piaget (1963, pp. 9-10, 40-41).

Time, Movement, and Velocity

One might assume that developmental progress in these three conceptual domains would show numerous interactions and synchronisms, given their definitional interdependencies, and Genevan theory and research here has in fact proceeded from just this assumption. Thus it is that Piaget's volume on movement and velocity (1946b) is regarded as the direct continuation of his book on temporal concepts (1946a), the two together comprising an extensive research report of about 20 developmental studies (see also Flavell, 1963a, pp. 316-326, Flavisse, 1963). This section will begin with a sketch of his views concerning the developmental construction of these concepts.

Piaget's Developmental Analysis of Time, Movement, and Velocity Concepts According to this analysis, the young child's intellectual representations of time begin by being thoroughly confounded with his representations of space. He tends to confuse successions of events in time and the resulting temporal intervals between these events with their spatial counterparts, that is, with the sequence of spatial points traversed in a movement and the spatial intervals or distances between these points. One way to demonstrate this confusion experimentally is to elicit comparative temporal judgments regarding two movements which are simultaneous and spatially parallel, but proceed at different velocities and hence cover different distances. The young child is very likely under these circumstances to deny the simultaneity of their starting and stopping, as well as the equality of the intervening temporal durations, because he mistakenly relies on purely spatial cues: the fact that the starting or stopping *spatial* positions of the two movements do not coincide, and that the *spatial* intervals traversed by each are not equal. As Piaget interprets such evidence, the young child implicitly regards each individual movement as having its own "local time" (1946a, p. 273), unrelatable to those inherent in other movements. One of the child's major developmental tasks therefore is to construct something analogous to the general Euclidian framework described in the preceding sections: an all-encompassing, "homogeneous time" (*ibid.*, p. 273) within which all movements proceed in common, and thus within which all movements can be ordered and compared on a common temporal basis.

The child's early conceptions of movement and velocity are equally discrepant from those he will eventually attain. Initially, both phenomena are indexed solely in terms of the perceived endpoints of spatial motions. In the case of movement, such indexing sheds further light on how the young child conceptualizes distance (see the previous section): one object is said to have moved further than another if it ends up ahead of the latter, regardless of the actual distances traversed. Similarly, accurate velocity comparisons are made only if the child can actually see one object pass, or end up ahead of another. If the passing occurs out of the child's sight, he is wholly unable to utilize the available time

and distance information to judge their relative speeds.

The forgoing analysis of the pre-operational child's capabilities in the areas of time, movement and velocity implies that there is much developmental work for him to do in succeeding years. The following is a paraphrase of the experimental topics treated in the two books, giving a fair idea of what Piaget thinks this work includes.

In the case of time, there is first of all a conceptual grasp of temporal order of succession and of the temporal intervals between succeeding temporal points—analogous to the ordinal and cardinal aspects of number, respectively. Other achievements include an understanding of temporal simultaneity, additivity and associativity of temporal intervals, the measurement of time through the construction of the temporal unit, and finally, what Piaget calls "lived" time, including the concepts of age and of internal, subjective time. In the case of movement, there are the concepts of spatial order, composition of displacements in space (distances), and relative movements. And for velocity, there is the notion of the time-distance relation and its ultimate measurement in a variety of situations: in successive versus simultaneous movements, for uniform versus accelerated motion, and in the case of relative velocities [the velocity of one object relative to that of another, simultaneously-moving object] (Flavell, 1963a, p. 318).

(Piaget's Research on the Genesis of Time, Movement, and Velocity Concepts One of Piaget's experiments well illustrates the young child's difficulty in keeping temporal estimates uncontaminated by spatial ones (Piaget, 1946a, Chap. 3). The child is shown two parallel "race tracks" on which two little "men" run. Starting even, one of the men runs a certain distance (call it a distance of 4 units) while the other one simultaneously runs a shorter distance (1 unit). Immediately thereafter, the second man runs again (1 more unit, say), while the first remains in place. Thus the facts are that the second man ran for a longer period of time and stopped running later than the first, whereas the first man ran the greater distance and ended up ahead

of the second Here is a 5½-year-old who interprets the situation differently

"What did you see?—The yellow one (I) stopped and the other one (II) walked again—Then which one stopped first?—The blue one (II)—Which first [E used "en premier" rather than "d'abord" in repeating the question]?—The blue one (II)—Which one walked for the longest time?—The yellow one (I)—Let's say that this one (I) stopped at noon Now look, did this one (II) stop at noon too, or before, or after?—Before—at noon" As a control procedure, we make the two movements go in opposite directions Both I and II leave from point A, but I goes to D_1 on the right while II simultaneously goes to B_2 on the left, II then continues on to C_2 All questions are now correctly answered I "stops first" and II "walked the longest" (*ibid*, p 91)

Spatiotemporal undifferentiation also plagues the pre-operational child's judgments about "lived" (versus "physical") time (*ibid*, Part 3), as the following study illustrates The child is shown two series of pictures representing the year-by-year growth of two fruit trees One of the trees is planted a year after the other but, growing at a faster rate, eventually outstrips the first in size, quantity of fruit, etc Young children tend to judge this tree to be the older of the two, disregarding then knowledge that it was planted later

Other investigations have dealt with the child's growing understanding of the metric properties of time, for example, that temporal intervals can be divided into subintervals which exhibit the properties of additivity and associativity For instance, the child only gradually comes to realize that two durations must be equal if their component subdurations are equal (additivity), and the same is true for the equivalence $(A + B) + C = A + (B + C)$, where A, B, and C are temporal intervals which occur in sequence (associativity)

The best known study in the movement category was described in the previous section (inversion of spatial order under 180°, 360°, etc, rotations) The others largely concerned the concept of distance, with the usual emphasis on the development of a metric, sum-of-units view of this property (Piaget, 1946b, Part 2) Tasks requiring an under-

standing of relative movements prove to be particularly difficult for children a snail moves along a board at the same time that the board moves along a table, in the same or opposite direction from the snail's movement, determine the net distance that the snail moves in relation to the table Correct solutions to this problem do not occur in force until around 11 to 12 years of age, and there are reasons to suppose that the requisite mental operations are formal rather than concrete (*ibid*, Chap 5)

As for velocity, the writer has previously described one set of Piaget's investigations in the following way

The first several experiments all bear on a single point that children initially reduce velocity to an intuition of order and changes of order, i.e., that object traveled faster which, initially behind another, caught up to it and ended up ahead We shall summarize these experiments by describing the typical reaction of the younger subjects to the velocity problem each experiment presented When two parallel and simultaneous movements of unequal speed and distance take place inside tunnels, so that the child cannot see the faster one gaining on the slower one, the child thinks they traveled at equal speeds When two simultaneous movements of unequal velocity and distance begin at a common point and end at a common point (the longer and faster one taking an angled or sinuous itinerary and the shorter and slower one following a straight-line path), the child believes the velocities were equal When simultaneous movements proceed along concentric circles (the movement along the larger circle being of course faster), the child asserts equality of speed When one object starts its movement at the same instant as a second but from a position considerably behind it, the young child will say it traveled faster if it ends up in front of the second when they both stop, but not if it ends up parallel to or just behind the second (in all three cases its actual speed was considerably greater than the second's) If two objects make parallel movements of equal distance, one starting before the other in time but both terminating simultaneously (termination points superimposed), the child either thinks the speeds were equal or else that the one which started first went faster,

since it initially "passed" the (stationary) second one in the beginning of its movement (Flavell, 1963a, p 324)

Children solve such problems with dispatch—but only once in possession of the necessary inferential machinery

Ner (8, 11) "The big one goes faster [the object travelling along the larger circle in the above-mentioned concentric circle problem]—Why?—Because it makes more of a trip in the same time" (Piaget, 1946b, p 141)

Other experiments dealt with the child's understanding of relative velocity, acceleration, quantification of speed, and the like. Similar to the experiment on relative movements, most of the tasks used here seem to require something more than concrete-operational thinking for their solution.

Other Studies There appear to exist only two broad-scale replications of Piaget's research in these areas, both by the indefatigable Lovell. One systematically repeated about a half dozen of Piaget's studies on time concepts (Lovell and Slater, 1960), the other did the same for virtually all of his velocity experiments (Lovell, Kellett, and Moorhouse, 1962). Predictably, these investigators observed roughly the same kinds of age-dependent immature and mature responses to these various tasks that Piaget found, and also the usual intertask variability in difficulty level. The congruence with Piaget's developmental findings appears to be particularly marked in the Lovell, Kellett, and Moorhouse study. With the exception of the one on spatial order (see Charlesworth, 1962), the small group of Piagetian experiments on the concept of movement appear not to have been systematically replicated yet.

Although only Piaget and his followers seem to have studied the growth of movement and velocity concepts, there exists a considerable extra-Piagetian literature on the development of temporal thinking (e.g., Ames, 1946, Bradley, 1947, Friedman, 1944a, 1944b, Oakden and Sturt, 1922, Springer, 1952, for reviews of this literature, see Fraisse, 1963, Jahoda, 1963a). It would be difficult to review most of this work with any enthusiasm, however. Largely atheoretical in orientation, these studies tend to focus on certain obvious and highly

phenotypical expressions of the child's grasp of time: his growing ability to cope with clock, calendar, and historical sequences, his evolving comprehension and utilization of time words ("yesterday," "next year," etc.), and the like. The results of these various studies do accord reasonably well with one another, and hence developmental generalizations about such behaviors can be made (see Jahoda, 1963a, for examples). The problem rather lies in trying to give these generalizations any theoretically interesting and meaningful interpretation. On the other hand, Fraisse's book (1963) provides an excellent survey and analysis of developmental changes—Piagetian and non-Piagetian, perceptual and conceptual—in this area. Although his views on the developmental psychology of time do not coincide with Piaget's on all points, their differences do not appear to be substantial enough to warrant review here.

Causality and Related Concepts

Previous chapter sections have reviewed studies of the child's developing conceptualization of certain measurable properties of the natural world's objects and events, properties like weight, length, area, time, and velocity. One might equally inquire into his evolving views about these objects and events themselves, as particular phenomena in that world. For example, how do children of different ages interpret the nature, origin, and activity of specific natural entities like shadows, night, sun, clouds, birth, life, death, and so on? There is a potential danger in posing such questions, however, since the number of investigatable entities here is practically inexhaustible. A determined but unreflective empiricist could readily find himself enmeshed in a multilifetime effort to trace the developmental course of this, that, and a hundred other specific concepts. A research program of this kind would be as poorly conceived as it is unfeasible, since its scientific yield would likely be very meager. A far better strategy would be to assess children's conceptual reactions to some carefully selected subset of the possible entities for the express purpose of diagnosing the nonspecific (i.e., to any particular entity) cognitive traits that underlie these reactions. This kind of strategy is a sensible one for any research enterprise, of course, but it is especially important where—

as in the present case—the risk of scientific nit-picking is particularly great

Piaget's Theory and Research on Children's Causal Explanations Early in his career, Piaget did a number of studies in which he elicited children's verbalized interpretations of diverse natural phenomena (1929, 1930). His scientific strategy was essentially the one just outlined: treat the child's particular interpretations of particular phenomena as symptomatic expressions of deeper-lying and more general cognitive tendencies—expressions of his "spontaneous attitude of mind" (Piaget, 1929, p. 123). The underlying tendencies or "attitudes" were conceived as existing at two levels. At the upper level are the child's tacit causal (initially "precausal") notions, it is these notions which at least partly determine how he answers Piaget's questions about various physical-biological phenomena (shadows, life, etc.). At the lower level, and in turn mediating his concept of causality, is the child's position on the developmental continuum from egocentric to socialized thought. Thus the child's ideas about causality are seen as a crucial intermediary between his implicit view of the natural world and the fundamental orientation of his mind. It is for this reason that there is much on children's world views in Piaget's *The Child's Conception of Physical Causality* (1930) and much on their causal thinking in his *The Child's Conception of the World* (1929).

The gist of Piaget's developmental theory here can be summarized as follows (Piaget, 1929, 1930, see also Flavell, 1963a, pp. 279–290, Laurendeau and Pinard, 1962, Chap. 1). An important manifestation of the young child's cognitive egocentrism is a relative undifferentiation between self and world, subjective and objective, psychological and physical. When his mind is directed toward genuinely psychological phenomena, this undifferentiation leads him to substantiate or "physicalize" these phenomena (a cognitive disposition which Piaget refers to as *realism*). Thus, for instance, dreams are initially conceived as external, palpable realities, potentially visible to others. When the child's mind turns to the realm of the genuinely physical, this same lack of differentiation leads him to the opposite kind of contamination, with psychological properties intruding into his conceptions of physical-natural phenomena. It is

this tendency to "humanize" the inorganic world that gets expressed in the variety of pre-causal "-isms" familiar to Piaget readers. Examples are *animism*—the attribution of life and consciousness to inanimate objects, *dynamism*—the attribution of humanlike energy, strength, and capacity for spontaneous movement to such objects, *finalism*—explanations couched in terms of anthropocentric functional purpose (boats float so that people can ride on them), and *artificialism*—the positing of a human or (humanlike) divine architect to account for the origin of natural objects and events (if lakes are thought to be dug *by* men, the belief is artificialistic, if they are thought to exist *for* man's use and convenience, the belief is finalistic; both beliefs may, of course, coexist in the same child).

The data base for these categories of pre-causal explanations was a series of interview, question-and-answer studies with children of various ages. These studies are probably familiar to most readers, and we shall simply allude to a few of the more salient findings. Young children may attribute life and consciousness to a number of inanimate objects, especially if they regularly show movement (e.g., wind and bicycles). Subsequently, these traits are restricted to entities whose motion is self-engendered (wind, but not bicycles). Artificialistic and finalistic answers are given to questions about the origins of natural phenomena like lakes, mountains, night, etc. For instance, night comes "so we may sleep." The movement of clouds is first conceived as the result of human activity, with the clouds themselves playing an acquiescent and cooperative role in the causal process (a combination of artificialism and animism).

Replications of Piaget's Research on Pre-causal Thinking This aspect of Piaget's research has had a much more troubled and uncertain career in the history of developmental psychology than have his other studies. Although there is much that we still do not understand about nonconservation of weight, say, there was not for long much dispute about its existence, as a readily elicitable response in young children, and about its decline with age. In contrast, both the existential and developmental statuses of pre-causal thinking have been subject to considerable controversy over the past four decades. As Laurendeau and Pinard's excellent survey

of this literature shows (1962, Chaps 2 to 4), some studies have failed to find any substantial amount of animistic, artificialistic, etc., reasoning in young children, whereas others report its presence in children and adults alike. Laurendeau and Pinard believe that both sets of discordant findings may be explained away on methodological and other grounds, and their own study was designed to settle the issue. Since this study appears to be the most thoroughgoing and careful normative-descriptive investigation of the subject ever done (or ever likely to be done), we shall summarize its procedures and findings. For a sample of other recent reviews and studies in this area, see Almy, Chittenden, and Miller (1966), Danziger and Sharp (1958), Jahoda (1958a, 1958b), Muuss (1961), Nass (1964), and Smith (1963).

Elaborate questionnaires were prepared on five topics previously investigated by Piaget: the concept of dream, the concept of life, the origin of night, the movement of clouds, and the floating and sinking of objects. The Ss were 500 French-Canadian children (Montreal area), 50 at each of ages 4, 4½, 5, 6, 7, 8, 9, 10, 11, and 12. The age groups were almost perfectly matched on a number of potentially relevant variables (such as sex and parents' occupational level), and the children at each age level comprised a representative sample of the local population. All Ss were tested individually by experimental examiners, either at school or at home (in the case of the youngest children). The children's answers to each of the five questionnaires were classified in terms of a Piagetian-type scale of developmental stages and substages. Three judges scored each response protocol, and interjudge agreement was very high.

The results of this study clearly support the conclusion that, when carefully questioned, young children do in fact give an abundance of the sorts of pre-causal explanation and interpretation reported in Piaget's early books, and also that these responses do in fact evolve and change with age in much the same way that he had originally described. Although Laurendeau and Pinard's data differed from Piaget's in certain details, the overall picture is decidedly one of consensus.

Not all the scales described by Piaget are found in the present classification. The differ-

ences noted are of two main types: either Piaget reserves a stage to answers too scarce or too ambiguous to characterize a real level of development (e.g., substantial formation of the night by dark clouds, explanation of life by the usefulness of objects, etc.), or else he does not provide a particular place for certain answers which are in fact truly typical and numerous enough to correspond to a normal level in evolution of a concept (e.g., anthropomorphism related to the concept of life, artificialism in the explanation of the movement of clouds, etc.). These divergences, however, do not prevent a recognizable and fundamental resemblance between our scales and those of Piaget. In both investigations, the child's conception of the world develops from a level of pure pre-causality to a level of objective causality through intermediate steps in which the opposite conceptions are intermingled (Laurendeau and Pinard, 1962, pp. 247-248).

The writer suspects that there may have been at least two factors responsible for the prolonged distrust of Piaget's findings in this and related areas. First, the *Zeitgeist* of the pre-1960s made for considerable resistance to the very idea that young minds might be qualitatively as well as quantitatively different from older minds, in the domain of causal reasoning or anywhere else. It is simply far easier for us today to imagine that the young child's causal thinking *might* have just the characteristics Piaget attributed to it, given everything else we now know about pre-operational thinking in general and childish egocentrism in particular (see the next section), one might even go so far as to say that an absence of qualitative differences here would be incongruous with our contemporary image of the developing child.

The second factor was probably a marked sense of discomfort in trying to diagnose tacit and subtle cognitive orientations on the basis of purely verbal interchanges with young children—organisms whose language-to-cognition circuits are still quite poorly engineered. It must be admitted that such discomfort seems as justified now as it did in the past, Laurendeau and Pinard's results notwithstanding, and Piaget himself has joined the rest of us in sharing it. In the preface to the Laurendeau and Pinard book, he states

In this respect, I must confess that had I been consulted, I would perhaps have attempted to dissuade my friends from such a return to precausality, not because I no longer believe in it, but because today verbal thinking seems to me marginal to real thinking which, even though verbalized, remains until about eleven or twelve years of age centered upon action (p. xii) exclusively verbal thinking therefore no longer seems to be sufficient for the investigation of the child's thinking—it provides a series of instructive indications, which must, however, be related to other findings derived from operational tests proper (p. xiii)

How could one investigate the child's causal orientation without asking questions about perceptually absent and, to the child, undoubtedly recon-dite phenomena like night and shadows? An ingenious study by Ausubel and Schiff (1954) suggests one possible approach. Kindergarten, third-, and sixth-grade children were presented with a teeter-totter bearing a red wooden block on one arm and an identical green block on the other. The task was to predict which arm would fall when released. Each child had two series of trials, given in counterbalanced order. In the "relevant" series, the longer arm (the one extending farthest from the fulcrum) always fell, just as the laws of physics say it should. In the "irrelevant" series, the arm which bears the red block regularly fell, for no explicable reason. The kindergarten Ss learned to make correct predictions in about the same number of trials in each of the two series, whereas difficulty of the irrelevant series becomes progressively more pronounced in the two older groups. Similarly, the learning of the irrelevant cause-effect relation is harder when preceded by the relevant series than when given first, but again only for the older children. The logic of this study is similar to that of the Youniss and Fuith (1965, 1966) experiments described earlier: make inferences about the child's cognitive skills and dispositions by seeing what he finds easier and harder to learn. This approach has much to recommend it when investigating the developmental growth of relatively nebulous and hard-to-articulate concepts such as causality.

Related Concepts There is a handful of studies, some developmental and some nonde-

velopmental, dealing with children's understanding of various biological phenomena: sexual anatomy (Kieitler and Kieitler, 1966), conception and birth (Kieitler and Kieitler, 1966, Nagy, 1953b), life (Safier, 1964, Steiner, 1965), various bodily processes (Nagy 1953a), germs (Nagy, 1953c), and death (Anthony, 1939, Nagy, 1948, Safier, 1964, Steiner, 1965). Most of these studies rather smack of the overspecificity and low-altitude empiricism that was cautioned against at the beginning of this section. The most significant contribution to the field of cognitive development is probably Safier's (1964) study (the Kieitler and Kieitler, 1966, paper has import for psychoanalytic theory). Safier's research suggests that there are some interesting parallels in the child's evolving concepts of life and death: both are initially pervaded by the child's animistic orientation, etc. Death itself is at first conceived as reversible, subsequently irreversible or permanent but escapable, and ultimately both irreversible and inevitable.

THE SOCIAL WORLD

After surveying the research literature on cognitive growth a few years ago, Wallach had this to say about intellectual development with respect to the social world:

In our examination of current research on the development of children's thinking, we obviously have concentrated on the child's knowledge of the physical world—i.e., on the traditional definition of thinking as reasoning, problem solving, and understanding, concerning the non-social environment. The extent to which thinking about the social environment follows similar or different ontogenetic patterns must remain an open question at this point (1963, p. 270).

The literature in this area is somewhat more substantial now than it was when Wallach's review was written, and the question he raises is correspondingly less open. There are in fact some indications that the "ontogenetic patterns" which are going to emerge here will turn out to be rather similar to those found in other conceptual areas. It is reasonable that this should be so. The mind of the child at any given level of its development would hardly be expected to change its basic design

features when turning from logical-mathematical or physical to social content. We shall try to convey a sense of this cross-content homogeneity in the sections below.

Psychological Concepts

The following passage from one of Piaget's books (1954) is a good point of departure for this section.

Intelligence thus begins neither with knowledge of the self nor of things as such but with knowledge of their interaction, and it is by orienting itself simultaneously toward the two poles of that interaction that intelligence organizes the world by organizing itself (pp. 354-355). In other words, the first knowledge of the universe or of himself that the subject can acquire is knowledge relating to the most immediate appearance of things or to the most external and material aspect of his being (p. 355).

Much of the research work already reviewed in this chapter supports the generalization that young children do not go beyond this "most immediate appearance of things" when reasoning about logical-mathematical and natural phenomena. It is only by penetrating the phenomenal surface, for instance, that the child can secure a conservation judgment in the face of countervailing appearances. What of Piaget's claim that the same is true for the self? Developmental research on the self-concept and related topics will be surveyed elsewhere in this book (see also Dubin and Dubin, 1965), but there are two pieces of evidence from Piaget's early work which we shall cite here. First, the young child's interpretations of his own psychological processes (notably, his daytime thoughts and nighttime dreams) tend to be "realistic" in the technical Piagetian sense, that is, these processes are construed as external-objective rather than internal-subjective in nature (Piaget, 1929, also recall the corroborative findings of Laurendeau and Pinard, 1962, in the case of dreams). Second, Piaget has also shown (1928, Chap. 4) that the young child is unable to gain access to his own cognitive processes, unable to treat his own thinking as an object of introspective thought.

Other human beings have features in common with both the self and with physical

objects. Like the self, other individuals are sentient organisms endowed with distinctive, subjective-psychological properties. Like non-social objects, they are "out there," external to the self. And like both, according to the research evidence of Piaget and numerous others, the child's interpretations of them begin with surface manifestations and only gradually move into the psychological interior. That is, he initially represents and reasons about those aspects of other people that are most accessible to direct perception, thereby neglecting the crucial but covert processes of thought, perception, attitudes, feelings, etc. Let us briefly survey Piaget's evidence first.

Piaget's Research on the Development of Psychological Thinking. Several of Piaget's investigations have dealt with the child's ability to represent the perceptual experience of another individual when that experience differs from his own (Piaget and Inhelder, 1958, Chaps. 6, 8, 9). In the best known of these studies (*ibid.*, Chap. 8), the child sits facing a scale model of three mountains and is tested for his ability to predict their appearance from various other perspectives (from the right of where he is seated, from the opposite side, etc.). The most interesting finding was that a number of the younger children kept confusing their own perspective with the others. Asked to find the photograph which represents how the mountains look from a given position, for example, the child tends to select the one that reproduces his own view. We have already described (Relations) how the pre-operational child's absolutistic and uniperspective egocentrism permeates his conceptual treatment of relational concepts such as "left" and "right," "brother," etc. (Piaget, 1928).

The cognitive experiences of other people are similarly underrepresented in the young child's thinking. For instance, he characteristically fails to pay attention to his listener's receptive capacities and informational needs when verbally communicating with him (Piaget, 1926). Because he does not monitor the listener's probable reactions to what he is saying and frame his messages accordingly, these messages tend to have an unedited, private-speech quality about them.

Finally, Piaget's data on moral development (1932) emphasize the young child's insensitivity to the inner motives and inten-

tions of others. The individual who steals a more costly object to give to a needy friend is judged more culpable by young Ss than one who steals a less expensive item for purely selfish reasons. Analogously, the "whopper" innocently perpetrated by a young storyteller is initially estimated to be a more heinous offence than a plausible untruth, which was, however, clearly intended to deceive its hearer. Thus, although the young child is able and ready to consider the overt and objective aspects of interpersonal situations, the covert motivational processes of the participants escape him.

As he grows older, the child becomes increasingly sensitive to the existence of covert perceptual, cognitive, and motivational processes in other people (as well as in himself) and also increasingly accurate in his identification and interpretation of these processes. Piaget (1928) believes that the major vehicle for the developmental decline of this and all other manifestations of cognitive egocentrism is social interaction, especially with peers. Conflicts, arguments, and other dissonant interpersonal experiences gradually compel the child to pay attention to perspective differences, and thereby eventually to generate some conceptions and information-gathering skills regarding human psychological processes.

Other Research. Although one would be ill-advised to write a textbook called *Social-Cognitive Development* on the basis of presently existing research data, there are at least the beginnings of a real literature in this area. Much of it has been stimulated by Piaget's pioneering studies, but the theoretical writings of Mead (e.g., 1947), Heider (1958), and others have also played a role. The writer and his associates (Flavell 1961, 1966a, 1966b, Flavell et al., 1968, Fry, 1966) have carried out what is probably the broadest-scale investigation in the area so far, and hence their work can serve as a convenient framework for reviewing the rest of the literature.

Flavell et al. have used the expression "role-taking activity" to refer to the processes under discussion, but "person perception," "interpersonal inference," "social cognition," or even the barbaric but apt "people-reading" might do as well. As we view it, role-taking activity may entail any of a number of per-

ceptual-cognitive processes in the role-taker, may take as its object any of a number of psychological processes in the other person, and may be carried out for any of a number of concrete purposes. Let us briefly amplify the latter two of these three features. The description of Piaget's work has already suggested that the object toward which this activity is directed can vary: the other's perceptual experiences, his cognitive experiences, predispositions, and capacities, his emotional states, his motives and intentions—in short, anything that people might construe to be a potentially "readable" or inferable psychological entity. Likewise, role-taking activity may be initiated for any of a variety of purposes in order more effectively to cooperate with the other person, to understand and be understood in communicative interactions with him, to compete with him, simply to satisfy one's curiosity about him—the list could obviously be extended to include any motive which this particular kind of information-gathering might help to satisfy. Our research was concerned with developmental changes in role-taking activity or skill across a sampling of objects and purposes.

One of our tasks was closely patterned after the Piagetian model-mountain problem, and thus was intended to assess the child's ability to predict visual-perceptual experiences different from his own momentary one. The data showed very consistent and regular increases with age in this ability across middle childhood and adolescence. Subsequent research with maximally simple perspective-taking tasks led us to think that the very notion of perceptual perspective or point of view is probably absent in most 3-year-olds, gradually emerging in rudimentary form during the preschool period. Developmental findings consistent with these and Piaget and Inhelder's data have also been reported by Davol and Hastings (1966), Dodwell (1963), Gellert (1966), Laubengayer (1965), and Lovell (1959). Karplus (1964) has devised an ingenious teaching technique involving perceptual role-taking to convey to elementary school children the relativity of position and motion, and Laubengayer (1965) has had some success in furthering the perspective-taking ability of preschool children through systematic training. Moore (1958) has also demonstrated that the development of perceptual role-taking

skill is not confined to the visual sphere older children are more sensitive than younger ones to what others may be hearing as well as to what they may be seeing

A different sort of task is needed to tap role-taking processes directed at the non-perceptual (e.g., cognitive or affective) experiences of the other person. In one of our investigations, middle-childhood and adolescent Ss are shown an ordered series of seven pictures which, in comic-strip fashion, illustrate a story. After the child has narrated the story, three of the pictures are removed. The remaining four pictures were so constructed as to suggest a story also, but this story is quite different from the original, seven-picture one. A second *E*, supposedly unacquainted with any of the pictures, now enters the room. S's task is then to predict the story that this *E* would derive from the four-picture series. There is of course no *perceptual* role-taking problem here, both *S* and *E* see the same four pictures, and in the same orientation. The problem is instead to predict *E*'s *cognitive* response to what he sees, that is, his interpretation of what the visual stimuli, in their ensemble, suggest or signify. We found that many second- and third-grade children (the youngest Ss in this study) could not accurately predict what story the four pictures would suggest to a naive other—one not "contaminated," as is the child, by having previously seen them in full, seven-picture context. A characteristic reaction is to predict cognitive responses to the four pictures which they themselves have come to make on the basis of previous experience (i.e., a seven-picture-story interpretation) but which the inexperienced other would be very unlikely to make, much as the young *S* in a perceptual role-taking task keeps misattributing his own perspective to the other observer. Another of our studies showed clear developmental trends in the ability to impute complex chains of reasoning to other people, particularly those that include a representation, by the other, of one's *own* cognitions—"I think that he thinks *that I think* such-and-so."

The data from these and other studies in the literature suggest that inferential activity regarding the cognitions, feelings, etc., of others changes with development in at least two ways. First, the child constructs an increasingly rich interpretation of the other's

covert processes, more—and more complex—internal psychological events are attributed to him as the child matures. Second, what gets attributed to the other also becomes more accurate and objective, less tainted by the child's own, egocentric perspective. Dymond, Hughes, and Raabe (1952), Flapan (1965), and Rothenberg (1967) have found a substantial increase across middle childhood in the child's disposition and ability to explain surface behavior in terms of subsurface cognitions, feelings, motives, etc. Feffer (1959) and Gollin (1954) have devised formal test procedures for assessing such dispositions and abilities, and have also reported developmental changes across middle childhood (Feffer and Kourevitch, 1960) and adolescence (Gollin, 1958). Milgram and Goodglass (1961) found a decided increase from second through eighth grade in S's ability to make accurate guesses about the normative word associations of young children and adults. The Baldwins and their students have recently begun to investigate the development of various interpersonal concepts, using as their frame of reference the average adult's implicit "theory" of human behavior as described by Heider (1958). Thus far reported are interesting age changes in the child's interpretation and assessment of malevolent-benevolent intentions (Baldwin, 1965), kindness (Baldwin and Baldwin, 1967), and fairness (Shure, 1967), the latter reminiscent of Piaget's work (1932) on moral judgment. Whiteman (1967) has done an interesting developmental study of children's conceptions of psychological causality (i.e., human motivation), using kindergarten and third-grade S's. Although not quite resembling miniature psychoanalysts, Whiteman's older S's did show a surprisingly good ability to sense the motivational workings of classic defense mechanisms (displacement, projection, denial, etc.) behind the overt behavior of a story character, for example, to understand why a child who does not like to share her toys might anticipate nonsharing motives on the part of other children whom she had never even met before (projection).

As Piaget's early research (1926) has shown, one of the most important functions or purposes of role-taking activity is the monitoring and guiding of communication behavior. A message constructed without any

attention to the informational needs and information-processing capabilities of the intended audience would only be accidentally effective. A number of our studies investigated developmental changes in the child's ability to tailor and adapt his verbal messages to particular listeners and circumstances. In one of these studies, Ss are given the task of explaining how to play a game to two adult listeners, one of whom can see the game materials and one of whom cannot (he is blindfolded). Older children construct much longer and more informative messages to the blindfolded listener, whereas younger children tend to say the same things to both. A few of the younger Ss went so far in their disregard of audience characteristics as to refer without further explanation to "this," "there," etc., when talking to the blindfolded listener. Similar age differences obtained in a study where the two listeners differed in cognitive (adult versus child) instead of perceptual (sighted versus blindfolded) receptive abilities. Other investigations showed developmental changes across middle childhood and early adolescence in the ability to (1) modify a message on the basis of postmessage feedback regarding its communicative inadequacy, (2) give a single, "lowest-common-denominator" message to several listeners who differ in initial informational level regarding the content to be communicated, (3) evaluate the adequacy of someone else's message, (4) communicate nonredundantly, and (5) construct an effective persuasive as opposed to informative message.

Recent studies by Glucksberg and Krauss (1967), Glucksberg, Krauss, and Weisberg (1966), and Krauss and Glucksberg (1965) have yielded very similar developmental findings. They too interpret the young child's communicative performance as reflecting an absence of editing and modification due to a failure to take note of the communication-relevant attributes of the listener. If this interpretation is correct, one would expect that role-taking and communication skills, independently assessed by means of two separate tasks, would covary within the individual. Such covariation has in fact recently been demonstrated, both in children (Cowan, 1966) and in adults (Feffer and Suchotliff, 1966; Phillips and Feffer, 1966). Role-taking ability has also been shown to correlate with other

variables. Swinson (1966) found significant correlations between Feffer's role-taking test and several of Piaget's concrete-operational tasks (e.g., conservation of quantity), with age, grade, and IQ partialled out. Rothenberg (1967) found small but statistically reliable correlations between social sensitivity and several measures of interpersonal adjustment and intelligence. Wolfe (1963) has further demonstrated significant interrelationships among several indices of role-taking ability. Other relevant studies in the area of interpersonal inference include Elkind (1967b), Kohlberg (1963), Muuss (1961), and Nielsen (1951).

As already suggested, we have much yet to learn about the ontogenesis of role-taking and related "people-reading" abilities. There is, however, enough evidence available to risk an educated guess about its major features.

We ought now to be able to make some speculations—likewise preliminary—about what this development consists of, and when in childhood its various constituents tend to appear. The nature of these constituents can be epitomized by considering what one needs to know, or know how to do, in order to engage in behavior which is mediated by role-taking activity. There are five such constituents.

- 1) The understanding that there is such a thing as "perspective," that is, what you perceive, think, or feel in any given context need not coincide with what I perceive, think, or feel (*Existence*).
- 2) The realization that an analysis of the other person's perspective is warranted in this particular situation, that is, such an analysis would be a useful means to whatever one's goal is here (*Relevance*).
- 3) How actually to carry out this analysis, that is, possession of the ability to predict with accuracy the relevant attributes of the other (*Ability*).
- 4) How to maintain in awareness the fruits of this analysis, in competition with the unremitting press of one's own point of view, long enough for it to be able to fulfill its function as means or instrumentality for subsequent behavior (*Performance*).
- 5) How then to employ the fruits of this analysis as a means to some behavioral end,

for example, as an effective monitor of verbal communication (*Application*)

The evidence suggests that the development of *existence* is at least partly accomplished by the beginning school years. Young preschoolers often behave as if the very existence of perspective variation were foreign to them, whereas many older preschoolers clearly demonstrate an awareness of its existence, at least in task situations where the experimenter's instructions and the elemental nature of the role attributes in question conspire to facilitate such awareness. Correspondingly, there is some *ability* to predict with accuracy those perspectives whose existence the child is mature enough to recognize, but this ability appears to be extremely limited—limited primarily to the discrimination of the more obvious components of the other person's perceptual perspective.

On the other hand, really substantial prowess in *ability*, and in *relevance*, *performance*, and *application* as well, is probably not attained much before late middle childhood or early adolescence. We have been impressed with how rudimentary is the capacity, during the early school years, to tune in on the hidden role-taking requirements of ostensibly non-role-taking (e.g., communication) tasks (*relevance*), to predict complex perceptual inputs and subtle or intricate intellectual processes in the other person (*ability*), to keep one's image of the other person's role attributes unsullied by one's own ongoing perspective (*performance*), and to translate what one knows or can guess about the other person into effective social behavior regarding him (*application*). In contrast, the child 12 to 14 years old in our studies and in other studies shows himself to be a surprisingly adept role taker across a wide range of tasks and problems. Although the data are really not yet ample enough to justify it, one is tempted to predict that middle childhood will turn out to be *the* developmental epoch so far as basic role taking and allied skills are concerned, with the preschool period contributing the prologue and adolescence the epilogue (Flavell, 1968a, pp. 175–176).

Other Concepts

A survey of developmental research dealing with logical-mathematical, physical-biological,

and psychological notions does not quite exhaust the existing concept-development literature. There is a small remainder, most of it concerned with the acquisition of political, economic, and religious concepts. The general tenor of this residual literature is suggested by Geis' remark in a recent book review: "The book will *certainly* be read by psychologists interested in political development, and *possibly* by *some* interested in cognitive and affective development" (Geis, 1966, p. 586, italics ours). That is to say, these studies do provide information of greater or lesser interest regarding the specific content area in question, but they typically contribute little to our overall understanding of cognitive development.

Politics. The handful of studies in this area can be sorted into two rough categories. One deals with the evolution of children's knowledge, attitudes, and interests regarding political figures and institutions. The other focuses on their developing sense of national identity, changing conceptions of their own and other geographical-political units (native city and country, foreign countries, etc.), and related topics.

The investigations of Greenstein (1961, 1965), Hess and Easton (1960, Easton and Hess, 1962), and O'Neill (1965) make up the first group. Greenstein and Hess and Easton administered survey questionnaires to large groups of middle-childhood and early-adolescent Ss, with very similar results (Greenstein, 1961). A general finding was that children develop strong feelings and opinions about political entities well before they achieve any clear understanding of them. They like and identify with a specific political party before learning how the parties differ, they think the President is extremely important and rate his performance in the job as superlative without any clear idea of what he actually does, let alone how competently he is doing it, etc. Images of the father and of the President are initially very similar, and Hess and Easton (1960) hypothesize that the President first emerges as a generalization from the father. The President appears to be the American child's earliest point of contact with the political system, with other offices and institutions initially apprehended in relation to him: the alderman, courts, legislature, and the like are perceived simply as the Pres-

ident's "helpers" (Greenstein, 1961) Gradually, the roles and functions of political offices become better understood and differentiated from their human incumbents Greenfield's (1965) data show that by eighth grade, rate of approval of the President's performance has declined to a level similar to that found in a national survey of adults O'Neill's (1965) interview study with an adolescent sample revealed some interesting developmental changes in political-philosophical concepts, such as the notion of a community, the nature and functions of government, and the idea of individual rights

The second group is chiefly represented by a fairly elaborate study of Jahoda's, done in response to an earlier investigation by Piaget and Weil (1951) The empirical aspects of Jahoda's work are presented in three articles (1962, 1963b, 1963c), with an overview and theoretical analysis given in a subsequent paper (1964) We shall eschew Jahoda's (1964) detailed (and generally well-founded) critique of the Piaget and Weil study in favor of suggesting some developmental conclusions derived from both sets of findings Young children are initially extremely vague about the denotation of their native city, state, and country and correspondingly confused about the partitive or inclusion relations among them Thus Glasgow and Scotland (Jahoda), or Geneva and Switzerland (Piaget and Weil), may be represented by the young child as discrete, nonoverlapping physical domains Similarly, the child may be unable to grasp the fact that he is at once Scottish and British (or Genevan and Swiss) Part of the problem could be a basic difficulty in handling the logical-inclusion operation (Piaget and Weil) However, a more powerful determinant after the child has reached early middle childhood would well be the abstractness and ill-defined character, for the child, of these geopolitical units (Jahoda) It goes without saying that coherent ideas and attitudes regarding foreign countries are not in evidence during this early period (Jahoda, 1962) Weinstein (1957) did a scalogram analysis of 5- to 12-year-old children's answers to a series of questions concerning national identity and the notion of flag He found a fairly well-defined developmental sequence of 10 steps or levels in the cognitive mastery of these political concepts

Economics Schuessler and Strauss (1950, Strauss and Schuessler, 1951) tested for developmental changes in the child's ability to identify coins, compare their values, and establish monetary-value equivalences among them Although clear age trends were revealed, this study deserves to be remembered more for its methodology than for its substantive findings so far as the writer knows, Schuessler and Strauss were the first to use scalogram-analysis techniques for assessing the sequential invariance of developmental stages A second study (Strauss, 1952) had a broader focus, dealing with the meaning and uses of money within the economic system The child only gradually sees, for example, that paying money and receiving change for goods bought from the storekeeper is more than a mere ritual, that there is a "maker" who sells goods to the storekeeper, that the "maker" and the storekeeper spend money received on a variety of things (more goods, their employees, items for personal needs, etc.), and that business is essentially an impersonal affair governed by the profit motive (a customer and a storekeeper need not like each other, a storekeeper sells goods for more than he pays for them—both these propositions often denied by young children)

The results of a later study (Danziger, 1958) roughly confirm Strauss' findings In addition, Danziger emphasizes that what the child initially lacks and only gradually attains is a conception of the economic world as a system of reciprocal relationships—of balanced exchanges of money, goods, and services between boss and worker, seller and buyer

Religion. The few existing studies on children's thinking in the area of religion well illustrate one leitmotif of this chapter the overall level of the child's intellectual development operates like a "g" factor in specific content areas to determine in part his conceptual structuring of these areas Goldman (1965), for example, had no great difficulty classifying children's interpretations of Biblical events (e.g., the temptations of Jesus) as reflecting Piaget's pre-operational, concrete-operational, and formal-operational modes of thinking, each class of interpretation predominating during its appropriate age span He therefore concludes "Religious thinking appears to take place, within the context of be-

belief in the supernatural, according to the same processes and methods of thinking as applied to other fields of experience" (p. 167). Elkind's developmental studies of Jewish (1961d), Catholic (1962b), and Protestant (1963) children's conceptions of their respective religious denominations makes the point even more strongly (see Elkind, 1964b, for a resumé and discussion of his findings).

In general, it was found that the *form* of the child's thinking at a given age/stage was remarkably consistent across the three groups, with the *content* showing the expected interdenominational variation. Moreover, the major formal changes are reminiscent of generalizations made in the previous section. For instance, the essential ingredients of one's religious identity are at first external (e.g., going to a certain church) and only later internal (e.g., possessing certain beliefs). The child's concept of prayer likewise exhibits this familiar developmental movement from outer to inner aspects (Elkind, Spilka, and Long, 1966). In the writer's judgment, Elkind's interesting studies have important implications for the field of religious education. Miscellaneous other investigations of children's conceptualizations of the social world include Case and Collinson (1962), Jahoda (1959), Meltzer (1925), Orban (1945), Pfleiderer (1964), and Spiegel (1950).

GENERAL ISSUES IN THE FIELD OF CONCEPT DEVELOPMENT

The major purpose of this chapter has been to review the basic, normative-descriptive literature on conceptual growth, concept area by concept area. Such a review fails to highlight certain issues, questions, and problems common to all of these areas, which are repeatedly encountered whenever a deeper analysis of any of them is attempted. The remainder of the chapter will do little more than simply introduce some of these problems and call the reader's attention to pertinent bibliography. In this instance, brevity is dictated by more than the everpresent space limitations. There is reason to doubt whether our knowledge and understanding regarding these issues is sufficiently advanced as yet to make possible any really extended and authoritative review.

Developmental Diagnosis of Conceptual Acquisitions

All research on concept development, whatever its ultimate purpose, involves developmental diagnosis at some point. The experimenter must always, by one testing procedure or another, try to assess the child's status vis-à-vis predefined conceptual item (skill, notion, structure, operation). Evidence is rapidly accumulating, however, that precise estimation of children's cognitive-developmental status is a much more complicated and nettlesome problem than we had once thought. One might until recently have believed, for example, that nothing could be more straightforward than to find out whether a young child is capable of transitive inference. The notion of transitive inference is clearly definable, and the Genevans have long since provided us with simple but elegant procedures for its diagnosis. However, a recent controversy between Brame and Smedslund (Brame, 1959, 1964; Smedslund, 1963a, 1965, 1966b; see also Gruen, 1966; Wortman, 1964) has shown that the assessment of this inferential skill is a veritable mare's-nest of conceptual and methodological problems. We are now led to wonder what testing procedures, if any, will protect us here against diagnostic errors of both the false-positive and false-negative variety. Moreover, it must now be asked whether transitive inference is a monolithic, all-or-none entity or whether, instead, there may be several earlier and later, less and more mature forms of it. Similar questions are currently being raised concerning the nature and measurement of other Piagetian acquisitions (e.g., Bruner, 1964; Bruner, Olve, and Greenfield, 1966; Gruen, 1966; Inhelder, Bovet, Sinclair, and Smock, 1966; Kohnstamm, 1967; Pascual-Leone and Bovet, 1966).

The classification and resolution of diagnosis-and-assessment problems in this field are crucial for a number of reasons. We shall cite only two of the more important ones. First, exact developmental dating is obviously a prerequisite for describing the temporal relations among conceptual acquisitions, in particular, which ones emerge in a regular ontogenetic order, one always before another, and which ones emerge more or less concurrently. Information about temporal relations is in turn a necessary (but not sufficient) first step in

determining the functional and structural relations among acquisitions. For instance, only if we could be sure that cognitive item *A* regularly precedes cognitive item *B* could we entertain the possibility that *A* might somehow help to mediate the attainment of *B*, might be an earlier and more immature form of *B*, etc. Similarly, only if we were certain that items *X* and *Y* developed in synchrony could we make hypotheses about the emergence of some superordinate structure upon which both depend. It is apparent that the functional and structural connections between, for instance, transitivity and other acquisitions cannot be even guessed at until we can decide whether it first appears at 4 to 5 years (Braine) or at 7 to 8 years (Smedslund and the Genevans).

Precise evaluation of the child's developmental status is also indispensable whenever we wish to assess the effects of experience on cognitive growth (for instance, the rapidly burgeoning ensemble of Piagetian "training studies"). The nature and magnitude, and hence the theoretical significance of training effects can be inferred only from information about cognitive status before and after the training experience. Much of the recent controversy concerning the influence of short-term experimental interventions on intellectual growth has hinged precisely on disagreements about the trainees' pretraining and posttraining intellectual structure (e.g., Kohnstamm, 1967, versus Pascual-Leone and Bovet, 1966).

Concern about diagnostic problems has resulted in the creation of a number of new testing procedures in recent years. Largely in reaction to reputed deficiencies in Piaget's "clinical method," many of these procedures require a minimum of verbal judgment and explanation on the part of the child. Braine (1959, 1962) has been an early and assiduous proponent of nonverbal methods here and has tried to devise procedures that will be sensitive to the first manifestations of a given acquisition. We have in previous sections mentioned the diagnostic innovations of Davies (1965), Goldberg (1966), and Yost, Sigel, and Andrews (1962) in the area of probability concepts, of Youniss and Furth (1965, 1966) with transitive inference, and of Ricciuti (1965) with early classificatory abilities. Charlesworth (1964, 1966, Charlesworth and

Zahn, 1966) has successfully employed surprise reactions as indicators of cognitive level in both infants and schoolchildren, and DeVries (1967) has done much the same with fear responses.

Also worth mentioning is an extinction procedure for evaluating the depth and solidity of conservation concepts, in which the child is presented with fabricated empirical evidence that appears to contradict his (correct) conservation judgment. The Genevans generally favor the use of such techniques, and have for years used verbal countersuggestion ("But another little boy told me . . .") for the same purpose. Invented by Smedslund (1961c), the extinction method has subsequently been used in studies by Brison (1965), Hall and Kingsley (1967), and Raven (1965). It has recently been criticized by Kohnstamm (1967)—probably rightly—as susceptible to assessment error of the false-negative variety (i.e., genuine conservers mistakenly diagnosed as nonconservers). In the writer's opinion, the current proliferation of new testing methods has done more to highlight the complexity of the developmental diagnosis problem than to clarify and resolve it. The road from observed test responses to conclusions about underlying structure remains a sinuous and treacherous one.

The fundamental difficulty appears to be one of conceptualizing, and subsequently finding ways to diagnose accurately, the different ways or senses in which a child may be said to "have" a cognitive item in his repertoire. Flavell and Wohlwill (1969) have recently suggested that Chomsky's (1965) competence-performance analysis of language behavior and development may also be useful in thinking about this and related problems in the area of intellectual development. Briefly stated, the argument is that any given conceptual item, for example, the notion of transitivity, may first emerge as a part of the child's intellectual "competence" considerably earlier than normal testing procedures would indicate. At this point in development, the item—while now genuinely "there," "in the system"—is conceived as being exceedingly fragile and difficult to elicit, highly vulnerable to blockage by innumerable "performance" factors (memory and attentional problems, interfering perceptual and conceptual sets, and

the like) In the ensuing years (and it is normally a matter of years rather than months) the item slowly frees itself from performance limitations, gradually becomes consolidated, stabilized, and generalized, and eventually emerges as a reliably elicitable cognitive tool in most appropriate situations and under most internal and external conditions of testing. It might therefore be, for example, that Braine's 5-year-old, Smedlund's 8-year-old, and an adult mathematician could all be said to "have" a transitivity rule—in contrast, say, to a 2-year-old—but they would be said to "have" it in quite different ways. If this general view of how conceptual development typically proceeds is even approximately correct, a great deal of painstaking research awaits us, because we know almost nothing as yet about the details of the process. For related ideas regarding the nature of cognitive development and for some possible examples of temporary performance limitations on competence during its course, see Aebli (1963), Beilin (1966), Braine and Shanks (1965a, 1965b), Davies (1965), DeVries (1967), Dodwell (1963), Donaldson (1964), Elkind (1966, 1967a), Feigenbaum (1963), Fleischman, Gilmore, and Ginsberg (1966), Goldberg (1966), Goodnow (1962), Halpern (1965), Huttenlocher (1964), Inhelder, Bovet, Sinclair, and Smock (1966), Lunzer (1965b), Maccoby and Bee (1965), Mermelstein and Shulman (1967), Murray (1965, 1966, 1967a, 1967b), Pascual-Leone and Bovet (1966), Pinard and Laurendeau (1969), Pratoomaj and Johnson (1966), Santa Barbara and Paie (1965), Siget, Saltz, and Roskind (1967), Smedslund (1960, 1964a, 1966c, 1966d, 1966e), Szeminska (1965), Vygotsky (1962, Chaps 5 and 6), Wallach and Spratt (1964), Wallach, Wall, and Anderson (1967), Wohlwill (1964b), Wohlwill and Katz (1967), and Zimiles (1963, 1966).

Developmental Sequences and Concurrences

As implied in the previous section, one of the major aims of cognitive-developmental study is to identify and interpret the temporal relations that may hold among conceptual acquisitions. For any pair of acquisitions *A* and *B*, the most interesting of such relations are invariant concurrence (*A* and *B* develop synchronously in all children) and invariant sequence (e.g., *A* develops earlier than *B* in all

children). There appear to be methodological problems in the initial empirical identification of invariant concurrences and sequences, conceptual problems in formulating reasonable hypotheses to explain them, and further methodological problems in the subsequent testing of these hypotheses. Much of what will be said about these problems derives from previous writings by Joachim Wohlwill and the present author (Flavell, 1966c, Flavell and Wohlwill, 1969, Wohlwill, 1963, 1966a, see also Pinard and Laurendeau, 1969).

Sequences How can we ascertain whether one intellectual acquisition (*A*) invariably occurs earlier in childhood than another (*B*)? The crudest and least certain method is to show that the mean age at which a test for *A* is passed is lower than the mean age at which a test for *B* is passed, each test given to a different but roughly comparable sample of *Ss*. Many of Piaget's initial claims about developmental sequence (and concurrence) were based on such data. An obvious improvement on this method is to compare mean ages (or equivalent indices of difficulty level) when both tests are administered to the same sample (e.g., Beard, 1963a, 1963b, Beilin and Franklin, 1962, Elkind, 1961a, 1961b, 1961f). However, even within-sample comparisons of mean ages are insufficient in themselves to demonstrate *invariant* (i.e., exceptionless) sequences, because such comparisons would fail to detect a possible minority of out-of-sequence *Ss*, namely, children who pass test *B* but fail test *A*.

A more powerful measure of sequential invariance therefore would be one that scrutinizes the test response patterns of individual *Ss* for sequence reversals. Whereas a few reversals might be written off as measurement error, more than a few would suggest that the sequence under study is not truly invariant. There are now quite a number of studies in the literature that have analyzed pairs of cognitive acquisitions (e.g., conservation and transitivity of length) in essentially this fashion (e.g., Chittenden, 1964, Dodwell, 1960, Hyde, 1959, Keats, 1955, Kooistra, 1965, Lovell and Olgivie, 1961a, 1961b, Lunzer, 1965a, Piaget and Inhelder, 1941, Raven, 1965, Shantz and Smock, 1966, Sigel and Mermelstein, 1966, Smedslund, 1961b, 1961f, 1962, 1964a, and Wortman, 1964). When sequences of three or more acquisitions

(e.g., conservation of mass, weight, and volume) are tested for invariant order of emergence, one or another version of scalogram analysis is generally used, but the basic logic remains the same (e.g., Davol, Chittenden, Plante, and Tuzik, 1967; Dodwell, 1961; Escalona, 1966; Goldman, 1965; Goun-Décarie, 1965; Kofsky, 1966; Lunzer, 1960b; Nassefat, 1963; Peel, 1959; Raven, 1965; Schuessler and Strauss, 1950; Smedslund, 1961f, 1962; Uzgris, 1964; Uzgris and Hunt, 1966a, 1966b; Wallace, 1966; Weimstem, 1957; Wohlwill, 1960). It would be expected that unambiguous-looking instances of sequential invariance thus identified in cross-sectional data would also be confirmed by longitudinal study, where an S's progress from A to B can be assessed directly. Escalona (1966) has in fact obtained this kind of confirmation in the case of the sequential growth of prehension skills in infancy (see also Almy, Chittenden, and Miller, 1966).

If our views on the problems and pitfalls of developmental diagnosis are as realistic as they are pessimistic, however, not even the most sophisticated of available testing and data analysis methods can assure an accurate identification of invariant sequences, particularly where the developmental onsets of the A's and B's in question are closely adjacent in ontogenetic time. Suppose, for example, that it is really (i.e., genotypically) the case that some A invariably begins its development shortly before some B does. Suppose further that our test for the presence of A in children's repertoire is, quite unknown to us, systematically less sensitive than our test for the presence of B, that is, it yields a higher percentage of false negatives. If these two tests were administered to a sample of children in the appropriate age range, the probable result is a substantial percentage of sequence reversals—children in whom both A and B are in fact evolving, but who pass the "easier" test for B and fail the "harder" test for A. Conversely, if the test for B were the less sensitive, an investigator might be led to infer an invariant A-B sequence when the genotypic facts were quite different (even including the possibility of an underlying B-A invariant sequence). It should be noted that longitudinal studies provide no inherent safeguard against such interpretation errors, as long as the two tests retain these properties

If A were a much earlier acquisition than B, to be sure, differential sensitivities are likely to cause no difficulty, on the other hand, a finding of sequential invariance here would probably be of less theoretical interest. What we need, obviously, is some means of equating the "hit rates" of the tests we wish to compare. This may be possible when dealing with certain kinds of acquisitions, as Smedslund's (1964a) excellent study has tried to demonstrate in the case of conservation (A) and transitivity (B) of weight. Whether this kind of essential control can be enacted in all cases is uncertain at present (Flavell, 1966c). Where it cannot, the confidence level of an invariant-sequence assertion might be increased somewhat by utilizing a variety of different tests for each of the acquisitions being compared.

The empirical demonstration that some A reliably precedes some B in ontogenesis ought to be regarded as only the beginning of the developmentalist's task. The next step would obviously be trying to hypothecate an other-than-temporal connection between A and B, which could account for, or at least make plausible, the observed temporal one. There has been surprisingly little attention given in the literature to this aspect of the problem (Flavell and Wohlwill, 1969). For a formulation somewhat different from the one very tentatively proposed below, see Piaget (1957).

The A's and B's whose temporal relations have been or could be investigated are a most heterogeneous lot, comprising any and all conceptual milestones that our current pre-theories have defined for us. Correspondingly, the possible developmental liaisons among them that could be envisaged are also quite varied.

In many cases, there appears to be some kind of recognizable structural similarity between earlier A and later B. For instance, B may constitute a more perfected version of A—more stable, more generalizable, and more readily available to the child when the problem setting calls for it. Some of the adjacent pairs of stages in the evolution of the object concept and the conservation concepts might be cases in point. Alternatively, B might be a richer structure which has incorporated its predecessor as a subpart. Formal operations are related to concrete operations in this way

In general, the developmental processes of differentiation and integration postulated by Werner (1948) and others are likely to result in sequences of cognitive items linked by one or another form of similarity or partial-identity relation.

There are other ordered acquisitions which exhibit no such similarity. The most important subcategory here includes sequences in which *B* effectively comes to replace or substitute for a quite different-looking *A* as the dominant mode of response to a certain class of stimulus situations. For instance, more mature forms of moral judgment gradually preempt less mature ones, with the only essential similarity between the two being the content area to which they apply (i.e., moral problems). More extreme cases of this general category are largely without interest: those pairs whose members are so dissimilar in structure, function, and age of acquisition that their invariant order of appearance invites no effort at explanation, say, the object concept (*A*) and the concept of proportionality (*B*).

There is a third and extremely interesting category of *A-B* liaison, which, although sometimes difficult to distinguish from the first, has more of a functional than structural quality about it. In this instance, the relation of *A* to *B* is essentially that of means to end or mediator to mediated. *A* evolves first, and sooner or later thereafter plays a key role (together with other mediators, perhaps) in the formation of *B*. Piaget's theory provides a number of alleged examples: a grasp of situation is said to be one of the developmental bridges to an operational concept of number, the ability to multiply relations (e.g., coordinate height and width) is thought to help mediate conservation of liquid quantity, etc.

This third category poses more of a problem for the developmentalist than do the other two. Once we have established empirically that mastery of visible displacements invariably precedes that of invisible displacements (stages 5 and 6 of the object concept, respectively), for instance, few psychologists would doubt that the developmental relation between the two is essentially one of what we have termed similarity or partial identity, with the later formation constituting an elaboration-generalization of the earlier one. Likewise, once we have evidence that, say, the child's first moral judgments are always absolutistic

and that they become progressively more relativistic with age, some sort of substitution-replacement characterization appears to be mandated. In neither case, of course, have we thereby told the whole developmental story. In particular, we have not described the mechanisms within the child or the forces within his milieu which help account for the transition from stage 5 to stage 6 and from absolutism to relativism. Nonetheless, we do appear to have specified the other-than-temporal, formal nature of the observed temporal relation in a largely incontrovertible fashion.

The situation is quite different where an invariant sequence looks as though it might reflect a mediational linkage. Even if careful research could convince us that, for example, the ability to coordinate height-width relations is invariably present before the child attains conservation of liquid quantity (there is no such convincing evidence at present, by the way), we still could not be at all sure that the one plays any developmental role in the formation of the other. The fact that the former ability might be a logically plausible mediator of the latter is obviously not good enough. The ability to coordinate relations is only one of a number of plausible candidates that have recently been put forward in the case of substance conservation, and we simply have no way of knowing at present which of them, if any, actually assists in the real-life genesis of that concept (Wallach, 1969). Moreover, what may be plausible or even logically compelling for one psychologist need not be for another. For instance, Smedslund thinks that the empirically identified sequence, conservation of length prior to transitivity of length, "also makes good sense logically" (1964a, p. 28), but the present writer finds his argument unconvincing.

It is apparent, then, that if empirical research is initially required just to identify *A* as a possible universal mediator of *B* (quite obviously, any substantial number of observed *B-A* sequence children would rule out even the possibility), additional research must be carried out to show that it is so in actuality. The most convincing research demonstration here would probably take the general form of showing that the experimentally induced and thereby accelerated acquisition of *A* is regularly followed by an accelerated acquisition of *B*. Such research is beset with numer-

ous methodological problems in practice, and unambiguous data on mediation are hard to come by (as only one of many cases in point, see Wallach, Wall, and Anderson, 1967). These problems are primarily the familiar ones of diagnostic assessment discussed previously, and they include those of ensuring that developmental movement really occurred with respect to both *A* and *B* subsequent to one's experimental intervention, and occurred *only* with respect to these (i.e., ensuring that the intervention did not as an unwanted by-product engender the development of some *X*, which might have done the real mediative work *vis-à-vis B*). If reasonably unambiguous positive findings could be obtained by such an experiment, however, the truth status of the hypothesized mediational linkage approaches that which can be bought more cheaply for other linkages. The aforementioned study shows that *A* *can* help to mediate *B*. Add to this the initial research finding that *A* invariably precedes *B* in normal development, and one is probably as close as one will ever get to proving that *A* routinely *does* help mediate *B* in the developmental histories of live children.

This is all that we shall say here about the sequence issue, but it is clearly not all that should be said. For instance, the exact definitions of and distinctions among the three types of relation just described remain extremely vague and uncertain and so, consequently, does the assignment of instances to each. We have also said nothing directly about the (likely) possibility of multiple mediators of a given *B* and of multiple "mediatees" of a given *A*. And, last, there is the question of the existence of noninvariant mediators (*A* helps to mediate *B* for some children but not for others) or, more generally, that of alternative developmental "routes" to any cognitive attainment (Flavell, 1966c), whether the milestones along these routes be linked by similarity/partial-identity, substitution, or mediation. Assuming that such questions have real referents, the study of concept development is assured a long if trying future.

Concurrences. The identification and interpretation of developmental concurrences has had a theoretical motivation quite different from that which underlies the search for developmental sequences, although the overall theoretical context is again Piagetian. Accord-

ing to Piaget, each of his three major developmental periods has two particularly significant features. Let us use the period of concrete operations as an example, since the concurrence issue has most often been raised in connection with that epoch. First, there emerge within this period a number of new intellectual operations of enormous power and generality, in the sense that each one can serve as a solution procedure for a large and extremely varied assortment of superficially unrelated tasks or problems. The number of different problems that might implicitly call for the operation of class multiplication for instance, would be vast indeed. Thus each operation is conceived as being profoundly genotypical, a veritable "cardinal trait" of cognition. The second important feature is that these operations are definitely not seen as leading separate and independent lives in the child's repertoire. Rather, they are said to be intimately connected, one with another, to form operational structures or systems. Sets of concrete operations are interlinked to form tight structures called "groupings," for instance, and these groupings are in turn conceived as variously interrelated. Piaget's term for the whole network of interrelated structures characteristic of a given developmental period, *structure d'ensemble* (e.g., 1955), conveys this sense of unity and interdependence.

The existence of developmental concurrences becomes an important theoretical issue given the validity of a certain line of reasoning with respect to what has just been said. We shall present this argument in its extreme form, although various weaker versions of it have been proposed or debated (useful sources here include Brame, 1959, Flavell and Wohlwill, 1969, Lunzer, 1960, Pinaud and Lauendeau, 1969, Wohlwill, 1963, 1966a). If, in the first place, any given operation has the profundity and generality which Piaget's theory ascribes to it, then its acquisition should be manifested by the child's sudden ability to solve any and all cognitive tasks to which it is applicable. In other words, the picture ought to be one of pronounced developmental concurrence across this ensemble of tasks—either consistent success or consistent failure, depending upon whether the child has or has not yet acquired the underlying operation. If, in the second place, these highly gen-

erial operations are also bound together into structures (with these structures in turn tightly interlinked), then one would likewise expect developmental synchronisms across operations. As soon as a child can master any task requiring one operation, therefore, he should be able to master any other task requiring any other operation, whether it belongs to the same grouping or not. To the extent that developmental reality fails to accord with this ideal picture, that is, it presents numerous asynchronisms within and between operations, to that extent would such key Piagetian expressions as "stage," "operation," and "structure" become imprecise and even misleading.

The research methods typically used to probe for concurrences are closely related to those employed in the identification of sequences. The investigator looks for high correlations among different tasks calling for the same operation or among measures of different operations. Equivalently, for a pair of noncontinuous measures he expects to find no more than a few Ss in the (pass A-fail B) and (fail A-pass B) cells of the fourfold table (if only the latter cell were near-vacant, one would of course have evidence for an A-B sequence). How often have predicted within-period concurrences been found by such methods? In the words of the Pinafore's captain—"hardly ever." Biame (1959) and Lovell (1961) have reported developmental consistencies in the case of certain concrete- and formal-operational skills, respectively, but asynchronisms of all within- and between-operation varieties have been the general rule (e.g., Beard, 1960; Chittenden, 1964; Dodwell, 1960, 1961, 1962, 1963; Kooistra, 1965; Lovell & Ogilvie, 1960, 1961b; Lunzer, 1960b; Mannix, 1960; Nassefat, 1963; Smedslund, 1964a; Swinson, 1966; Uzgiris, 1964; Wohlwill and Katz, 1967). Moreover, as Wohlwill (1963) has noted, a number of these asynchronisms may prove to be instances of invariant sequence.

It should be pointed out, however, that the empirical identification and theoretical interpretation of between-operation concurrences in particular are beset with many of the difficulties previously described in connection with sequences. On the methodological side, for instance, there is the familiar problem of differential test sensitivity. As in the case of se-

quences, this factor could lead us to misdiagnose an asynchronism as a synchronism or, more often perhaps, the converse. There are also questions of interpretation, given an indisputable-looking instance of concurrence. It would be at least conceivable that the two operations in question were unrelated or only very distantly related, despite their simultaneous appearance, for example, temporally coincident way stations on two parallel but independent developmental "tracks." More probably, however, consistent synchronism would suggest some kind of functional connection. It might be that both operations have some of the same mediators in common, or (and) reciprocally mediate each other during their evolution. If the observed concurrence really reflected a high degree of functional interdependence, any experimentally induced developmental progress in one should be accompanied by similar progress in the other, whereas this should not be the case if the two were only coincidentally synchronous.

According to the argument outlined earlier, data on developmental concurrences ought to provide vital evidence for or against Piaget's assumptions about the generality and the structural interrelatedness of cognitive operations, and hence for or against his general view of the nature of intellectual development. If the analysis set forth in the preceding paragraph is basically correct, there is reason to question whether an empirical finding suggesting concurrence in the case of two different operations is *sufficient* evidence for a structural relation between them. The concurrence might, as we have seen, be entirely coincidental. Even if it were not, there might be no plausible structural connection between, say, certain pairs of operations which owe their synchronism only to a common underlying mediator. The much more important point, however, is that it is hard to see why concurrences should be taken to constitute *necessary* conditions for the validity of *either* the generality *or* the structural-interrelatedness assumptions.

The matter of generality vis-à-vis a single operation (or any cognitive item, considered as an isolated entity) has really been dealt with in our previous discussion of developmental diagnosis and sequence. Everything we know about intellectual development continually forces us to distinguish between the

potential generality of any cognitive tool and the child's current ability to exploit that potential. Although it is still far from clear just how the developmental lag between early buddings and later blossomings ought to be conceptualized (our competence-performance conception appears only a little less inadequate in this respect than Piaget's original notion of horizontal *décalage*), it is simply a fact that the full evolution of any cognitive item almost invariably looks more like an extended process than a punctate episode. To use developmental concurrences as a criterion for the generality of an operation is really to confuse generality with generalizability—two quite different things in the case of an evolving mind. For a single operation within the concrete-operational period, then, the best statement would seem to be that this period is the segment of childhood *during which*, or *by the end of which*, this particular kind of operation *acquires* much of the generality and stability that it has in adulthood.

There are similar difficulties with the concurrence test as applied to the structural-interrelatedness question. It is perhaps symptomatic of these difficulties that recent treatments of the question have tried to liberalize this criterion. For instance, Pinard and Laurendeau (1969) argue that all the constituent operations of all the concrete-operational groupings should become more or less simultaneously effective within any given conceptual domain (e.g., all the operations underlying conservation, transitivity, measurement, etc., in the domain of weight), but not across all domains at once. In contrast, Wohlwill (1966a, see also Flavell and Wohlwill, 1969) has suggested that only the operations within a given grouping might be expected to emerge concurrently, thus allowing for the possibility of asynchronisms among the different groupings. However, a closer analysis of "structural interrelatedness" and equivalent expressions suggests that this criterion might better be abandoned altogether.

What does it mean to say that cognitive operations X, Y, and Z comprise a cognitive "structure," or are "structurally interrelated" within the child's cognitive system? For most psychologists, it would probably imply several things. First, the theorist-observer is able to characterize the structural relationships among the operations in some formal way,

for example, show that they can be modelled by a mathematical group, as with certain Piagetian structures (see Gyr, Brown, and Cafagna, 1967). Second, the operations do indeed coexist in the child's system, that is, he has acquired these operations. Finally, they do not *merely* coexist but also interact psychologically in some fashion. For instance, one might perhaps expect that the operation of uniting subordinate classes to form a superordinate class "calls to mind"—is associatively linked with—the inverse operation of redifferentiating the superordinate into its subordinate classes for any child whose cognitive system contains the concrete-operational grouping of class addition. Similarly, the engagement of either operation might also be expected to lower the threshold for operations from related groupings such as class multiplication. In other words, the external, logical-mathematical relations among operations should be paralleled by some kind of internal, psychological ones, if we are to claim that they constitute unified structures (*structures d'ensemble*) rather than simply a set of psychologically independent abilities. An important and still unresolved research problem is to find ways to confirm (or disconfirm) the psychological reality of the structures Piaget has described.

What "structural interrelatedness" does *not* seem to imply, however, on either logical or psychological grounds, is that the operations in question have to enter the repertoire synchronously. I assume that my knowledge of developmental psychology is in some sense a cognitive structure rather than a collection of independent pieces of information. However, it would be factually wrong to argue that this structure abruptly emerged at a given point in my adult development—elements, relations, and all—and logically absurd to claim that, since it did not, it could not *now* be a genuine structure. Similarly, no one would want to argue that adult linguistic operations do not constitute a complex structure merely because, as all evidence suggests (e.g., Klima and Bellugi, 1967), the components of this structure are acquired piecemeal rather than all at once. If Piaget's theory is correct, the normal child *comes to* acquire the full set of, say, concrete operations during middle childhood, and these operations *come to be* organized as psychological structures, it is theo-

retically unnecessary and probably empirically false to claim also that all these developmental events transpire concurrently. Much more, and much better research evidence will be needed before the full developmental story for this or any other period can be told, but it might have the following general character. Some sets of operations may regularly begin their evolutions more or less synchronously, perhaps because they have underlying mediators in common or perhaps because they tend to mediate one another. Other sets may emerge in fixed sequence, as a consequence of mediational connections of a unidirectional sort. Still other operations may show no invariant temporal relations at all. Each operation, whenever and however inaugurated, will require a more or less extended period of consolidation and generalization before it becomes reliably serviceable to the child across tasks and content areas. Either during this whole process or during the latter part of it, the evolving operations become psychologically interconnected, this too probably taking place in a gradual and stepwise manner. Only when the process is completed (if, in fact, it ever gets fully completed) will the child's cognitive system present most or all of the features described in the theorist's idealization of it. This image of how development proceeds suggests the following, not entirely facetious proposition. If you really want to study a Piagetian concrete-operational structure in all its power and glory, choose an adolescent as your subject—or better yet, a bright adult!

If the various same-stage acquisitions need not and probably do not show a really tight developmental synchronism, it cannot be denied that they do show at least a looser kind. Although the temporal gap between the evolutions of two concrete operations might be 3 years, for example, it clearly would never be 10 years. There obviously is some kind of glue that binds acquisitions together in ontogenetic time, albeit not as closely as we had once thought necessary, and its ingredients need to be analyzed. The most likely explanation here seems to be the Piagetian one that all within-period skills are of the same general kind, are at the same "level" in some specifiable way. For instance, concrete operations are conceived as internalized, symbolic actions (in contrast to sensorimotor actions), which take external data rather than other operations

as their objects (in contrast to formal operations). Furthermore, each period is regarded as necessarily prior to the one that follows it, with successor integrating predecessor (e.g., Piaget, 1967b). These conceptions together with all the preceding ones may thus serve to explain why a cognitive-developmental period is not a temporal point, why it is likewise not synonymous with all of childhood, why it occurs roughly when it does, and—more generally—why its postulation represents a substantive claim about the nature of intellectual development.

✓ Organismic and Environmental Factors in Concept Development

The concluding section of this chapter will attempt little more than a summary of the major questions underlying the search for organismic and environmental factors in concept development, a rough categorization of the types of research studies which have been designed to answer these questions, and the citation of relevant bibliography. The questions can be divided for exposition's sake into those focusing primarily on the changing organism itself and those emphasizing its developmental environment or milieu.

On the organismic side, the principal question is essentially the following: what design features of the immature human organism make possible the characteristically human patterns of intellectual growth described in this and other *Manual* chapters? No such growth would be imaginable unless the child's basic "program" contained special processes or mechanisms that would somehow permit, if not ensure, significant, nonrandom changes in that program during childhood. On the environmental side, the questions concern the contribution of external information and other sorts of input to developmental change, since no one believes that these processes and mechanisms operate independently of inflow from the milieu. We therefore also want to know, among other things, what kinds of inflow play what causal role (e.g., constitute necessary and/or sufficient conditions) in the operation of these processes vis-à-vis what segments of conceptual growth. Since the effects of environmental factors have been given a great deal of attention by developmental psychologists, especially in this country, it is worth emphasizing that the growth-making

activities of the child himself must remain one of our most fundamental subjects of study. In this connection, our scientific objectives might well include a kind of ethological characterization of the course of human conceptual growth, one emphasizing those underlying processes and surface conceptual outcomes that are species-typical, in the sense of remaining essentially constant over a rather wide range of human environments.

The organismic-environmental distinction can also be applied to the research literature in this area (although not always effortlessly). Some studies show a relative emphasis on the child's own capacities and activities, whereas others pay particular attention to milieu variation and its effects. Cross-cutting this division is a second, more cleanly dichotomous one. Some investigations involve active attempts to engender developmental change, whereas others take it as they find it. The contrast is the familiar one between experiment and study, or between intervention and nonintervention, where the emphasis is upon environmental effects, it could be rephrased as a distinction between programmed and unprogrammed inputs to the child's conceptual growth.

Studies. Noninterventionistic studies have investigated the developmental influence of several organismic variables. Predictably, IQ has been one of them, with most studies finding some positive association between this warhorse factor and, for example, performance on various Piagetian tasks (e.g., Dodwell, 1960; Feigenbaum, 1963; Goodnow and Bethon, 1966; Hood, 1962). A potentially more interesting variable is linguistic ability, since it has long been assumed that language development and conceptual development must interact in some fashion. So far as this writer can discover, no one has yet formulated the possible nature of this interaction in any really clear and precise way, particularly with respect to putative influences of language acquisition on conceptual growth. Furth's (e.g., 1964, 1966) recent studies of cognitive development in the deaf strongly suggest that the acquisition of a linguistic system (defined broadly to include, for instance, a codified gesture language of comparable structural complexity) cannot be a *necessary* condition for the growth of human thinking, at least up to the level of concrete operations. Further

research will be needed to clarify some alternative possibilities that come to mind: that (broadly-defined) linguistic abilities have some weaker, facilitative function up to that level, that they might play a stronger, perhaps even indispensable role in the more abstract realm of formal-operational thought (Pettifor, 1964), and, generally, that they assist the growth and continued operation of some kinds of cognitive activities much more powerfully and directly than they do others. Other recent writings dealing with this murky issue include Brown (1965, Chap. 7), Bruner, Olver, and Greenfield (1966), Farnham-Diggory and Bermon (1967), Inhelder, Bovet, and Sinclair (1967), Lantz and Lenneberg (1966), Piaget (1967a, Chap. 3), Sinclair (1967), and Werner and Kaplan (1963).

There is one interesting individual-difference variable which so far appears to be lacking a research literature. Piaget's theory seems to imply that an otherwise normally endowed child who has a congenital incapacity for manual interaction with the environment (e.g., born without arms) would suffer a gross retardation of intellectual growth, since the theory assigns a very important developmental role to the infant's motor actions *vis-à-vis* surrounding objects (these actions subsequently becoming internalized as "operations," etc.). One would therefore like to see a case study report on the intellectual attainments of such a child, analogous to Lenneberg's (1962) report on the receptive linguistic abilities of a boy born without the capacity to make speech sounds. The writer's guess is that Piaget's theory would not fare well in this research encounter.

Environmental factors which have been considered include family background (socio-economic status, religion, etc.), cultural milieu, and schooling. We cite here only the bulk of available references on the effects of schooling-nonschooling (Bruner, Olver, and Greenfield, 1966; Goodnow, 1962; Goodnow and Bethon, 1966; Mermelstein and Shulman, 1967; Price-Williams, 1962) and cultural environment (Bruner, Olver, and Greenfield, 1966; Cowley and Murray, 1962; Goodnow, 1962, 1967; Hyde, 1959; Jahoda, 1956, 1958a, 1958b; Piaget, 1966; Price-Williams, 1961, 1962; Vernon, 1965). The influence of these two factors has generally been found to be quantitatively and qualitatively different from

task to task. While really satisfactory explanations for these variable effects are not yet in view, there have at least been some interesting recent attempts (e.g., Bruner, Olver, and Greenfield, 1966; Goodnow, 1967, 1969; Piaget, 1966). One of the major problems with all such research, of course, is the difficulty one has in translating global characterizations of the child's environment (e.g., "has had no schooling," "is growing up in a Wolof village") into specific descriptions of the developmentally relevant life experiences he has undergone. The recent work of Hess and Shipman (1965) is an example of how at least partial translations of this kind can be effected.

Experiments. A complete inventory of investigative efforts to influence the child's intellectual growth would take us deep into the trackless wastes of educational research. We propose instead to consider only a certain group of such experiments, a group that is short on history but rather long on contemporary interest: laboratory or quasi-laboratory attempts to foster the acquisition of Piagetian concepts. The paradigmatic experiment here begins with a pretest diagnosis of the child's initial status vis-à-vis the concept or concepts of interest, proceeds to a brief (e.g., 2 hours), individually administered training experience of some kind, and concludes with one or more repetitions or elaborations of the original diagnostic procedures in order to assess the effects of the training. The implicit assumption in most of these experiments is the following: if a particular developmental change *can* be generated by the essential components of a given training procedure (provision of a certain kind of environmental information, activation of a certain type of organismic process, or whatever), then it is probable that this same change *is* regularly so generated in real life. Although this assumption has a certain plausibility in the case of some of these studies (but not in all), there is of course always the risk for the investigator of mistaking the sufficient but atypical for the necessary or normative.

The number of these Piagetian training studies has increased markedly during the past 5 years. There appears to have been only about a dozen of them completed by 1961-1962 (Flavell, 1963, pp. 370-379). It is doubtful if anyone knows exactly how many have been carried out since (a number of

them are described only in unpublished theses, for instance), but there must be a total of at least five dozen by now. The following list of relevant sources should therefore not be regarded as exhaustive: Anderson (1965), Beilin (1965, 1966), Beilin and Franklin (1962), Beilin, Kagan, and Rabinowitz (1966), Biame and Shanks (1965a, 1965b), Brison (1965), Bruner, Olver, and Greenfield (1966), Carbonneau (1965), Churchill (1958a, 1958b), Feigenbaum and Sulkun (1964), Flavell and Wohlwill (1969), Fleischmann, Gilmore, and Ginsburg (1966), Fournier (1965), Fry (1966), Gagné (1966a, 1966b), Gilmore (1966), Gréco (1959, 1963b), Guen (1965), Hétu (1966), Inhelder, Bovet, Sinclair, and Smock (1966), Inhelder, Bovet, and Sinclair (1967), Karplus (1964), Kohnstamm (1963, 1965, 1967), Langer (1967), Lasry (1966), Laubengayer (1965), Morf (1959), Northman (1964), Ojemann and Pritchett (1963), Ojemann, Maxey, and Snider (1965a, 1965b), Pascual-Leone and Bovet (1966), Piaget (1964a—see also Piaget's chapter in this book), Pinaud and Lauendeau (1969), Pufall (1966), Shantz and Sigel (1967), Sigel, Roeper, and Hooper (1968), Sinclair (1967), Smedslund (1961a, 1961b, 1961c, 1961d, 1961e, 1961f, 1963b, 1963c, 1963e, 1963f, 1964b), Stendler (1967), Suchman (1960), Thier, Powell, and Karplus (1963), Wallach, Wall, and Anderson (1967), Wallach and Sprott (1964), Wohlwill (1964a, 1966a, 1966b), Wohlwill and Lowe (1962), Wynns (1967), and Zmiles (1963).

Our earlier distinction between organismic and environmental research orientations becomes very strained when applied to this group of experiments. The purest example of an organismic variable here would perhaps be Piaget's hypothesized process of equilibration of cognitive actions, since the emphasis is on what the child actually *does* vis-à-vis stimulus input rather than on the particular nature of that input itself or on its manner of delivery. On the other hand, the investigator must also pay very careful attention to these latter factors if he really expects to elicit this supposedly formative, "spontaneous" process in a laboratory setting (Beilin, 1965; Carbonneau, 1965; Fournier, 1965; Guen, 1965; Inhelder, Bovet, and Sinclair, 1967; Langer, 1967; Smedslund, 1961e, 1961f, 1963e, 1963f,

1964b, 1966a) Conversely, the researcher who is more interested in the nature and mode of presentation of environmental information (e.g., Anderson, 1965) must, it would seem, eventually speculate about the particular kind of machine that could make developmental progress in the course of processing this information

This Janus-faced character of the training study is also expressed in the multitude of potential scientific uses it may have. Given the right design and unequivocal results, we could variously conceive of it helping us to understand, in the case of the cognitive device (child) as a whole, how this device is constructed at any given developmental level, what it characteristically does with environmental inputs in order to change its current structure, and what type, form, and range of information from the milieu will sustain or elicit this growth-building activity. And in the case of any particular hallmark of that device (e.g., a conservation concept), it could help us understand what its underlying components are, and how these particular components might have entered the system (again, by what organismic processes and vis-à-vis what environmental inputs). Most if not all of these scientific aims find their expression somewhere within the existing literature, and other variations could be mentioned. For instance, training studies might be used for purely diagnostic purposes, with the training being regarded only as a useful procedure for stripping away performance obstacles in order to make manifest the child's underlying competence (in rather the same way that psychotherapy can be thought of as one route to better diagnosis). Recent research by Braine and others (e.g., Braine and Shanks, 1965b) has some features of this approach.

Similarly, it would be worth exploring whether the effectiveness of a given form of training depends, not only upon the child's initial developmental status vis-à-vis the target concept (the familiar "readiness" notion), but also upon the general developmental period he is in and, consequently, the general *kind* of skill he is to acquire. Verbal-didactic methods, for example, might prove more effective for teaching formal-operational skills to preadolescents than for teaching concrete-operational skills to preschoolers, because of the basic differences involved in what is to be learned and in what kind of organism does the learning.

In what measure have existing training studies realized the scientific potential we have somewhat optimistically ascribed to them? A vague generalization must suffice in lieu of a properly detailed and documented statement to a very limited extent only. The basic requirements for a good training study are simple enough in principle: exact specification of initial cognitive status, of final cognitive status, and of intervening inputs and processes. For reasons frequently mentioned in previous sections, however, these requirements are extraordinarily difficult to meet in practice, and even the most careful and sophisticated of the available training experiments (e.g., Fournier, 1965, Inhelder, Bovet, and Sinclair, 1967—each reader of this literature would have his own favorites) raise more questions than they answer. It may seem a tite and lame ending to this chapter to say that much more really good research is needed, and that really good research always seems to be the hardest kind to do. Nonetheless, nothing could be truer of the whole area of concept development at the present time.

*The Development of Language**

DAVID MCNEILL

like the humors of the mind, the development of a child may be divided conveniently into four parts

One part is physical maturation. Another is personality development, including the process of socialization. A third is intellectual development. And a fourth is language development. The division is artificial but useful, created because of its advantages for orderly inquiry. However, it should not be viewed to obscure the fact that the four parts twine in complex ways to make up a process absolutely unique in the animal kingdom—human growth.

It is clear, for example, that socialization depends on the acquisition of language. Yet it is equally clear that language bears the fruits of socialization, as the linguistic differences among social classes attest. The develop-

The research for this chapter was supported by Grant # 5 PO1 HD 01368-03 from the National Institute for Child Health and Human Development, and by Contract # OEC-3-6-061784-0508 from the U.S. Office of Education, both with The University of Michigan, and by the Advanced Research Project Agency # SD-187, and the National Science Foundation # GS1153, both at Harvard University.

Ms. Meredith Kimball of The University of Michigan performed stalwartly in preparing bibliographic information, Dr. Kalon Kelley of the Massachusetts Institute of Technology, Dr. Dan Robin of the University of California at Berkeley, and Dr. Ursula Bellugi-Klima of the University of California at San Diego gave the author a critical reading, Mr. J. W. MacDonald at Harvard University was helpful on phonological matters, Mrs. Nobuko B. McNeill was helpful on other matters, and Mrs. Mavis Atamian rendered excellent secretarial service.

ment of personality both acts on and reacts to the development of intellect, as evidenced by the cases where both fail in schizophrenia (Inhelder, 1966). Indeed, although the interaction is rarely examined, the network of characteristics we call personality could not develop at all were it not for a child's capacity to represent his world in the particular way that forms the subject matter of cognitive psychology. Yet there are also differences in cognitive style, in the characteristic modes of thought that accompany particular types of personality (Kagan et al., 1963).

This chapter is concerned with two such interactions. One is between the acquisition of language and the growth of intellect. The other is between both of these and the process of maturation. The parts so intertwined may strike the reader as an arbitrary selection. However, the selection is a sensible one, and the interaction among them provides considerable insight into the process whereby a child becomes an adult. But this is the substance of the chapter.

PLAN OF THE CHAPTER

To understand the acquisition of language, it is essential first to understand something of what is acquired. There is, therefore, a Linguistic Appendix. Readers unfamiliar with developments in modern linguistics are urged to begin with it, others may want to refer to the Appendix only as the occasion requires.

The phenomenon of language poses a challenge for psychologists. A grammar is a system of knowledge. It is everywhere complex and at many points abstract. Yet very young children acquire grammars, and they do so in

a surprisingly short period of time. For reasons to be discussed in the first section of the chapter, various theories of development cannot account for this achievement. Explanation must follow other lines. One view is that the acquisition of language rests on certain linguistic capacities (which are reflected in language as linguistic universals). These capacities may be innate and may mature with time.

The bulk of the chapter is a survey of language acquisition itself. It is organized under three major headings, one for each of the three main components of a grammar: syntax, phonology, and semantics. A description will be given of the methods typically used in studying the development of each component, then the emergence of the components themselves will be traced, insofar as this is known, finally, there will be a discussion of various theoretical issues in the light of the empirical findings presented. Wherever possible, mention will be made of children exposed to languages other than English, with the chief contrast languages being Russian and Japanese.

A Caveat. There has been no serious attempt to survey the literature on language acquisition in a comprehensive way. This chapter is organized on principles other than inclusion. First, most of the references are recent. McCarthy's review (McCarthy, 1954) should be consulted for the earlier work. Moreover, recent developments in linguistics pose important issues for psychology, and examination of them takes priority within the limits of space over comprehensive citation. The criteria for including studies in this chapter, therefore, have been two: that they have not been covered by earlier editions of this *Manual*, or that they contribute in some way to the clarification, definition, or resolution of theoretical questions raised by the process of linguistic development.

SYNTAX

One major issue can be stated immediately. Normal children, not impaired by deafness, brain damage, or other physical or psychic disorders, begin to babble at about 6 months, utter a first "word" at 10 to 12 months, combine words at 18 to 24 months, and acquire syntax almost completely at 48 to 60 months. All children pass such a sequence of "mile-

stones," always at roughly these same ages (Lenneberg, 1967). They do so regardless of the language they acquire, or of the circumstances under which they acquire it. Such massive regularities of development remind one more of the maturation of a physical process, say, walking, than of a process of education, say, reading. One might even say that children cannot help learning a language, whereas they can easily avoid learning to read.

The acquisition of language thus shows some of the characteristics of physical maturation. Yet, at the same time, it is obvious that language is learned. Without certain linguistic experiences children acquire no language at all—as in the case of congenitally deaf or criminally neglected children.

One psychological issue, then, deals with the explanation of this peculiar combination of facts. The regular development of language strongly suggests the operation of a maturational process, as Lenneberg (1967) has argued recently. The complete absence of language in children deprived of all linguistic experience equally suggests a process of learning. Both learning and maturation are necessary conditions for the development of language, but neither is sufficient. To understand such a problem, clearly we must consider both the innate and the acquired aspects of linguistic competence, as well as the way in which they combine.

Nativism and Empiricism in Developmental Psycholinguistics. The question of what is innate and what is acquired in behavior and language is often posed in the same terms one would use in describing the selection of a wife. Except for polygamous societies, a person can have only one mate—either potential wife A or potential wife B must be chosen. Similarly, many wonder if language is innate or acquired. These questions are raised on the assumption that there is some reason to choose between the two alternatives, as if the truth about language acquisition required advancing one view at the expense of the other. In fact such questions are of marginal interest. The promotion of one of these views over the other merely serves the cause of obfuscation, not of truth.

The dichotomy between nature and nurture has been a pernicious one for psychology. It is pernicious because it has mainly polemical

value and obscures a far more basic question of the *interaction* of innate abilities with experience. One must suppose that there is a correct view of the latter, although of course it may not yet have been discovered. Whatever this correct view is, however, it is logically independent of the argument over whether language is largely innate or acquired. The two questions are quite distinct. It is misleading to state what children learn in acquiring a language without understanding what is in-born, conversely, it is misleading to state what is innate in language without understanding how it interacts with experience. Only one hypothesis is reasonable, not a pair of rival hypotheses. However, nearly all the debate over the existence of an innate endowment for language acquisition has rested on the dichotomy of innate and acquired aspects of language, and not on the question of how the two interact.

The Problem of "Cognition and Language"
Given that the basic problem in explaining language acquisition is to understand how the innate abilities of children interact with their linguistic experience, there remains a need to consider such theories of learning and cognitive development as are currently available, and whether or not they can account for this interaction.

For reasons considered at various points in the Linguistic Appendix and in this section on syntax, theories of learning based on S-R principles are inappropriate to the task. The acquisition of language involves the development of abstract linguistic knowledge, and there appears to be no way without question-begging to apply a theory couched in terms of "S" and "R" to a phenomenon where neither "S" nor "R" can be defined. For a number of strong arguments on this point, see Chomsky (1959), for a defense of S-R theory, see Osgood (1968), Palermo (in press), and Staats (in press).

Theories of cognitive development, such as Piaget's, cannot be dismissed so easily. There are no priori reasons to doubt the appropriateness of these theories to language acquisition, the problem instead is an empirical one. For each such theory we must ask whether or not the facts of linguistic development can be understood in the terms offered by the theory.

Such an inquiry, when it succeeds, would

make a fundamental contribution, for it would explain an aspect of the universal form of human language on the basis of general psychological principles. Let us call this enterprise the problem of "cognition and language" to distinguish it from the exactly opposite question of language influencing thought, which historically has been called the problem of "language and cognition."

The problem of cognition and language has not been widely recognized. There is little or nothing written of it. Moreover, the impression of this reviewer is that little or nothing could be written of it. The most comprehensive theories of cognitive development take the general form of language for granted; they do not regard it as a phenomenon to be explained. Vygotsky (1962) and Bruner (1966), for example, have concentrated on the opposite problem of language and cognition. Piaget (1926, also Sinclair-de Zwart 1967) has dealt with the expression of thought in language—which again is not the problem of "cognition and language."

Although occasional aspects of Piaget's theory may help explain fragments of language acquisition (such as the fusion of early speech with action, which seems to reflect the operation of sensory-motor intelligence), successes are rare and always leave one wondering if a reformulation of the cognitive theory would not lead to a stronger grip on language.

The immediate prospects of explaining the acquisition of language are bleak, but not hopeless. One can reverse the direction of exploration. Can the aspects of linguistic development that lie beyond psychological explanation be construed as matters of cognitive development? And if they can, then how might our theories of cognitive development be enriched to include the new cognitive phenomena? We shall encounter two outstanding examples of such a possibility. One is predication and the other is the set of transformational relations that universally exist between the deep and surface structures of sentences in all languages. Both are prominent in the acquisition of language, and yet neither apparently can be explained in terms of any cognitive theory.

It is important in this context to maintain a distinction between two kinds of linguistic universal. We shall call the two "weak" and "strong" (McNeill, 1969).

Weak Features that automatically appear in language because of conditions existing outside language, e.g., in cognition or perception

Strong Features that appear in language because of peculiarities of the human communication system itself, and so are not caused by general cognitive or perceptual abilities

There exists no way a priori to tell into which of these categories a particular linguistic universal falls. A linguistic description does not tell us *why* a feature is universal.

The importance of the difference between the two kinds of linguistic universal should not be overlooked. Only weak universals are relevant to the problem of cognition and language, a theory of cognition would be in error if it explained strong universals. Consider predication: well-formed sentences in every language must contain a subject and a predicate, the two being related by predication. *Mary* alone and out of context is not a sentence, whereas *Mary sings* is. In Japanese also, *Mary* alone and out of context is not a sentence, but *Mary-wa utamasu* is. Languages differ, often radically, in the form taken by predication, but they do not differ in the sense that any language fails to include it. We may wonder, therefore, if predication appears universally in language because it is imposed by a general cognitive ability, or if there is instead a universal linguistic ability to *express* predication. In the second case, linguistic predication belongs to the category of strong universals, and we expect to find examples of "cognitive predication" in the absence of linguistic predication—among animals, for instance, or among very young children. In the first case, however, linguistic predication is a weak universal and therefore should appear when nonlinguistic predication appears and must be included in any attempt to explain the development of language on the basis of the development of cognition.

The problem of cognition and language is not pursued in this chapter. Nonetheless, the reader is invited to bear it in mind as he follows the development of language, as it is set forth in the following pages.

We now turn to the development of syntax.

Methodology and Methodological Issues

There is little in the study of language acquisition that can be called Methodology,

with a capital M. The very speed of linguistic development constrains the methods used in studying it. Massive changes in the grammatical status of children take place between 1½ and 3 years. The age at which studies can be conducted is thereby fixed, and it is no one's fault that this age falls at a time for which there is, in general, no well developed methodology. In such circumstances, the simplest methods—for example, turning on a tape recorder—are as good as any, and the bulk of recent observations has been collected in this way.

Recent studies of the development of syntax can be organized in terms of three contrasting strategies.

1. Observers have examined either the production or comprehension of speech.

2. They have attempted either to trace general linguistic advancement or the emergence of particular grammatical systems.

3. They have conducted either experimental studies or made observations of spontaneous linguistic behavior.

Of the eight possible categories of methods formed in this way, only four have been used at all, and most studies have used just two. There have been no studies, for example, of general comprehension. Most have worked with spontaneous linguistic production, following the development of either general linguistic competence or particular linguistic systems. Certain strategies naturally go with others, comprehension, for example, has almost always been studied experimentally. With the exception of Sinclair-de Zwart (1967) there have been no studies seriously attempting to relate linguistic development to intellectual development, which is, perhaps, a fourth strategy, as well as a substantive issue.

Rather than make a list of the extant categories of research methods—a list that may change tomorrow—it seems more profitable to discuss the broader categories of research that present certain methodological issues.

General versus Particular Analyses The richest details and the deepest insights have so far come from longitudinal collections of observations. Such studies follow general linguistic development as well as the emergence of particular grammatical systems. Very often the same project lends itself to both strategies, so their proper relationship must

be understood. But first a word on the studies themselves.

Almost without exception, observational studies have been engaged with the production and not the comprehension of speech. All are descendants of the early diary studies long conducted by newly parental linguists (Stern and Stern, 1907, Leopold, 1939, 1947, 1949a, 1949b), and they differ from the earlier work mainly in the use of other people's children and in the collection of tape-recorded protocols. Brame (1963a), Weir (1962), Brown and Bellugi (1964), Miller and Ervin (1964), McNeill (1966b), and Gruber (1967) have all contributed varying amounts to this literature.

Typically, a small group of children is visited, at home, once or twice a month, where everything the child says and everything said to him, is tape recorded. The recordings are usually supplemented by running commentaries, made on the spot, describing the general situation in which the speech was uttered. The ultimate step in such extralinguistic record-keeping is to place everything on film or television tape, a step recently taken by Bullowa, Jones, and Bever (1964). Longer intervals between visits are possible and, for many purposes, are as useful as the 2- to 4-week intervals customarily used. The reason for these visits is to acquire a corpus of spontaneous utterances from a child. The significant part of the study lies in the analyses made of the corpus so collected.

It is in the treatment of the corpus that the two strategies—the analysis of general linguistic development and the analysis of particular grammatical systems—differ. The decision to conduct one analysis or the other rests in part on certain methodological issues.

One can try to write a grammar that describes a child's complete corpus. The hope in this case is to capture his total linguistic system at the time the corpus was collected, without distortion from adult grammar. It is often done by performing a distributional analysis of the child's speech. The procedure followed is clearly described in Brown and Fraser (1964), Brame (1963a) also provides some helpful comments. Essentially, an investigator searches for words that appear in the same contexts, the assumption being that such words are members of the same grammatical class in the child's grammatical sys-

tem. Words with different privileges of occurrence are assumed to belong to different grammatical classes.

Suppose, for example, that a corpus collected from a 2-year-old contains the following utterances:

My cap
that cap
a shoe
that horsie
other dog
a daddy
big shoe
red sweater

One could conclude that the words on the left all belong to one grammatical class, the words on the right all belong to a different grammatical class, and the child's grammar at this point considers a "sentence" to be any word from the first class followed by any word from the second class.

Words are placed into the same categories in a distributional analysis when there are no systematic differences in their usage relative to other words—they then have identical privileges of occurrence. *My* and *that* belong together because they both appear with *cap*. *Horsie* and *cap* go together because they both follow *that*. *Cap* and *shoe* are semantically similar, or so one assumes, so words that they can follow—*my*, *that*, *a*, and *big*—are placed together in the first class, and words that can in turn follow these words—*cap*, *shoe*, *horsie*, and *daddy*—fall together into the second class. The similarity of *horsie* and *dog* justifies adding *other* to the first class, as does the similarity of *sweater*, *cap*, and *shoe*, which justifies adding *red* also to the first class.

As these examples make clear, the independence of distributional analysis from the analyst's own knowledge of language is limited. A distributional analysis does not insist on the co-occurrence of words in strictly identical contexts, but counts appearance in the context of meaningfully related words as co-occurrence also. Moreover, one assumes that nonoccurring combinations—for example, *that sweater* or *big daddy*—are allowed by the child's grammar but are not observed because of sampling limitations.

Having established what seem to be a child's grammatical classes, the rules of his

grammar are written to state the manner in which classes are combined—in this case, Class 1 + Class 2. More complex categories demand more complex rules, but in every case the rules merely summarize the patterns of categories observed in a child's corpus. Studies that have prepared distributional analyses in this manner are Braine (1963a), Brown and Fraser (1964), and Miller and Ervin (1964).

An important methodological question is raised by such investigations. An investigator combines individual utterances (*my cap, a shoe*, etc.) into categories through the application of certain principles of combination (shared privileges of occurrence), and then states the regularities observed among the categories so formed (Class 1 + Class 2 is a sentence). But none of this necessarily comprises a statement of a child's linguistic competence, his knowledge of language. It is a summary of his performance, whereas a statement of competence is a *theory* about what a child knows.

Moreover, there is serious question whether or not a theory of competence can ever be developed from manipulations of a corpus. Contemporary linguists deny that it can be done (see Chomsky, 1964; Lees, 1964, for a discussion of such investigations of child language). A corpus is incomplete, unsystematic, and (in the case of adults, at least) insensitive to a number of important grammatical distinctions. Insofar as utterances from children are limited in the same way, a distributional analysis will not lead to a correct description of competence, however neatly it may summarize performance, and there is no way to tell when a corpus is so limited. A distributional analysis at best provides a description of a child's grammatical classes, plus some hints as to his grammatical rules. A theory of competence that explains these classes and rules may well take an entirely different form, a phenomenon that we shall see repeatedly in the pages that follow. The most elaborate general analyses of child grammar go far beyond the distributional evidence of a corpus (e.g., Brown, Cazden, and Bellugi, 1968).

As a description of performance, distributional analysis is but one source of information among many. Other observations, dealing with other aspects of performance, are often

of equal importance, in some cases, they are more easily justified.

Among other sources of information are observations made under the second strategy mentioned above. Rather than attempt to describe the total corpus collected from a child at some point in time, one examines the emergence of a particular grammatical system as it is manifested at different times. Thus one might study the development of negation (Bellugi, 1964), or questions (Klima and Bellugi, 1966), or a host of other grammatical systems. The advantage of this strategy lies in the demands it places on observation, arising from the very fact that it does what a distributional analysis typically strives to avoid—it exploits the fact that adult grammar is the endpoint of linguistic development. A distributional analysis attempts to discover parts of a grammar from a corpus. The second strategy begins with a part of adult grammar and judges if there is sufficient evidence in the corpus to justify ascribing it to a child. The demands on the second strategy are weaker than the demands on the first, for it must only recognize the applicability of a known theory; it does not have to discover an unknown theory.

When an adult analysis cannot be ascribed to a child, one can still describe the sequence of events followed in reaching the adult system. Thus, for example, children first negate by saying *not want*, then *don't want some*, then *don't want none*, and finally, *don't want any* (Bellugi, 1964). At each point, one can say what a child lacks with respect to the adult system: he does not have auxiliary verbs, he does not have negative pronouns, and he does not have indeterminate pronouns, respectively. But one does not attempt to *discover* from these observations the child's grammatical system. That is a separate step—a matter of the investigator's invention, ingenuity, imagination, and good fortune. It is everything, indeed, except a matter of discovery.

The following quotation from Brown, Cazden, and Bellugi (1968) summarizes many of the dangers and opportunities of following either strategy when interpreting a corpus of utterances collected from a child.

We operate on the general assumption that the child's terminal state of knowledge is of

e sort represented by current transformational grammars. However, we do not simply tribute to each sentence that the child produces the analysis that would be appropriate to that sentence if it were produced by an adult if we were to do that the inquiry could be largely vacuous. Insofar as the child's particular sentence—and all related sentences—depart from adult forms the grammar is tailored to the departures. The most formative departures are analogical errors: commission such as *goed*. Harder to interpret, but still important, are errors of omission such as the absence of auxiliary *did*.

Omissions in a sentence are at least easy to detect but omissions in the distributional range of a form are harder to detect and harder to interpret since it is necessary to weigh the probability that an omission is simply a consequence of the size of the sample that has been taken. Finally all the errors that occur must be considered in comparison with conceivable errors that do not occur. Even this full procedure will not render the construction completely determinate in all respects. The indeterminacies are tentatively resolved by assigning the usual adult representation insofar as that representation does not depend on forms that have ever appeared in the child's speech (p. 31).

It is possible to carry the second strategy to the level of true experimentation. Instead of observing the spontaneous occurrences of particular grammatical features, one tries to evoke them. For example, Ervin (1964), working with W. Miller, tested children's knowledge of English plurals by presenting free-form figures made of wood, each named with a nonsense syllable. A child is first shown one such figure, perhaps shaped like a salt-ellor and called a *bunge*, and then is presented with a second figure exactly like the first. What does he call the two figures together—*bunge* or *bunges*? The latter would indicate mastery of the rule for the pluralization of English nouns ending in sibilants. The age at which a child demonstrates such mastery can be compared to the age at which he correctly uses such genuine plurals as *ranges*.

A similar method can be used to elicit the past-tense inflection of verbs. The procedure offers some uncertainty in this case, mas-

much as past time is difficult to exemplify perceptually. A failure to elicit a past-tense inflection may result from a failure of the experimenter to present the appropriate conditions, as well as from a failure of the child to add past-tense inflections when the conditions are right. Nonetheless, one can at least approach the problem by demonstrating a novel gesture, saying at the same time *I'll sit it*, and then asking a child what had been done.

A child's ability to change model sentences into transformationally related sentences—to change, for example, active sentences into passives—has been studied by Brown (1968), working with Anita Olds, by means of the "alligator test." Two adults, each with a puppet, engage in the following dialogue:

Bear	The cat chased the dog
Alligator	The dog was chased by the cat
Bear	The zebra pushes the hippo
Alligator	The hippo is pushed by the zebra

And so on. The alligator speaks only in passive sentences. After a child has witnessed such exchanges for a time, he is given the alligator and asked to play its part. The method can be extended to many kinds of sentences and to many kinds of relations among sentences. Bellugi (1967) suggests studying negation in this way; questions could be approached through the alligator also.

Bellugi (1967) has described a number of tests of negation, some for comprehension, others for production. All are suitable for use with young children. Since the variety of syntactic forms covered is quite large, only a sampling will be given here.

To test a child's comprehension of negatives affixed to auxiliary verbs, a child can be shown a doll with movable arms, one arm up and the other down. The child is told to make the doll fit either of the sentences, "the boy can put his arms down" or "the boy can't put his arms down."

To test a child's comprehension of negation used in Wh-questions, a child is shown an array of objects—a boy doll, an orange, an apple, a ball, a toy, a tomato, and an ashtray—and is asked "What can the little boy eat?" or "What can't the little boy eat?"

To test a child's comprehension of affirma-

tive pronouns (such as *some*) and negative pronouns (such as *none*), a child is shown a doll and a few blocks and is told to make the doll fit either of the sentences "The doll can push some of the blocks," or "The doll can push none of the blocks."

To elicit negative indefinite forms (pronouns based on *any*), a child is first shown a doll with a hat on its head and is told "Here is John. He has something on his head." The child is shown a second, hatless doll and is told "Here is Bill. What does he have on his head? He doesn't have _____."

Another technique is to give a child systematically distorted forms, the distortions being designed to bear on points of syntactic interest, and ask the child to correct the errors. For example, "he not touching it," can be corrected by a child who knows that in English negatives must be attached to auxiliaries, but not by a child ignorant of this fact.

The reader can exercise his own ingenuity in devising other tests. It would be well, however, to bear in mind Bellugi's admonition that such techniques serve only to supplement the findings obtained from children's spontaneous speech. Tests of linguistic competence can never be rich enough, subtle enough, or sensible enough to stand on their own.

Perhaps the best known test of children's productive abilities is the test devised by Berko (1958). A comparable test has been independently developed by Bogoyavlenskij (1957) for use with Russian children (see Slobin, *in press*). Berko investigated the development of the morphological inflections of English: plural marking of nouns, past-tense marking of verbs, comparative marking of adjectives, plus some others.

The test uses a set of drawings of exotic creatures doing ordinary things, or ordinary creatures doing exotic things. Berko used it with children 4 to 6 years old, although it has been used with children as young as 2 (Lovell, 1968). One drawing, for example, shows a shmoollike creature. It is introduced as a *wug*: "Here is a wug." Then two more are shown, the experimenter saying, "Here are two others, there are two _____," his voice trailing off, hoping to elicit a plural inflection. The test includes items presenting each of the conditioning phonemic environments of the plural and past-tense inflections

of English, so by the end, one has collected a complete sample of a child's morphological inflections.

Studies of Comprehension A second methodological issue involves the comprehension of grammatical forms—how it is to be investigated, and why. Unlike the first methodological issue, which involves the clarification of the proper role of an existing method, this methodological issue involves the clarification of the requirements of a method that does not yet exist.

There are several reasons for studying comprehension. As one of the linguists at The Fourth Conference on Intellectual Processes (Bellugi and Brown, 1964) pointed out, in comprehension the investigator knows what the input to the process is—it is the sentence comprehended. Thus when comprehension fails, the source of trouble can be located. The same cannot be said for production. What is the input for, say, *What I can do mommy?*

Moreover, even though the results of production are easy to observe, it is not always obvious what the observations mean. Does the fact that a child systematically excludes auxiliary verbs from his speech signify the absence of Aux from his grammar, or does it, on the contrary, indicate censorship of Aux from his speech in order to meet the constraints of an abbreviated memory span? Although these are matters of production, it is only through the testing of comprehension that such questions can be settled.

We shall now describe the few studies that have attempted to investigate comprehension, point out their limitations, and present some promising new techniques.

Brown (1957) demonstrated that certain of the major grammatical classes have semantic correlates for children. He used a test of comprehension that apparently has not been employed since. A child is shown a drawing of someone performing a strange action with a peculiar substance contained in an odd bowl. The picture thus presents an action, a mass, and a container—three states that would be described in English by a verb, a mass noun, and a count noun, respectively. As the picture is shown, the experimenter says what it is: it shows *how to wug*, or *some wug*, or *a wug*. Whichever the child is told, he is next shown three drawings—one of the action

alone, one of the mass alone, and one of the container alone—and is asked to select the one that portrays what was labeled in the first picture. To the degree that a child is sensitive to the referential implications of verbs, mass-nouns, and count-nouns, he will be able to make appropriate choices (but see Briane, in press, for a different interpretation). Brown used this test with nursery-school children, finding them to be sensitive to the implications of each grammatical class. In view of the claim sometimes made (e.g., Slobin, 1966a) that children first construct grammatical classes on a semantic basis, it would be useful to repeat the experiment with younger, say, 2-year-old children.

A second test of the comprehension (as well as the production) of speech appears in an experiment by Fraser, Bellugi, and Brown (1963). Their method has come to be called the ICP Test, for Imitation, Comprehension, and Production. Again a set of drawings is shown to a child, this time in pairs. Each pair presents a referential correlate of some syntactic contrast—for example, subject versus direct object (a boy pushing a girl and a girl pushing a boy). In all, 10 different contrasts are represented. Comprehension is tested by saying to a child, "Here are two pictures, one of a boy pushing a girl, and the other of a girl pushing a boy," care being taken not to show which picture goes with which sentence. The child is then asked to point to the picture that illustrates one of the sentences. "Show me the picture of the girl pushing the boy." The test of production begins in the same way, but instead of asking the child to point to the picture for a sentence, he is asked to give a sentence for a picture. Fraser et al. conducted their study with 3-year-olds. Lovell and Dixon (1965) have done it with 2-year-olds, with much the same results.

Shipley, Smith, and Gleitman (n.d.) have studied comprehension in children as young as 18 months by giving them commands and observing whether or not the command is followed. Bever, Mehler, and Valian (1967) have used a similar method. In the case of Shipley et al., the commands are either well-formed by adult standards (e.g., *throw me the ball*) or are typical child-forms (e.g., *ball, throw ball, Please Johnnie, throw ball*). In addition, a given command might contain

only words known to a child (as in the examples above) or it might contain one or more words novel to him (e.g., *gor ball, throw ronta ball, gor ronta ball*). A major difficulty with the method resides in the identification of comprehension. Except when a child performs exactly as instructed, there is no way to tell if he has successfully analyzed a command or merely has responded to a part of the command, for example, to the noun. In commands using novel words, obviously it is impossible for a child to perform exactly as instructed.

Such studies of comprehension, clever though they sometimes are, suffer a common limitation. All use portrayable correlates of various grammatical contrasts and classes. But not every aspect of syntax has a portrayable correlate. Indeed, most of syntax cannot be so represented, as the reader can persuade himself by a glance at the Appendix. It is always possible, of course, that further ingenuity will discover more grammatical forms that can be tested in this way. However, this is of little significance, for as the method is extended further, it must use more and more remote connections between language and portrayable events. The methodological problem is to devise tests of comprehension that make use of the linguistic materials themselves, not the fortuitous correlations between language and the external world.

Two studies that point in this direction are Bellugi's (1965) and Brown's (1966). They searched their longitudinal records for spontaneous dialogues between children and adults, looking at the children's answers to the adults' questions. The aptness of the answer was the index of comprehension. If an adult asks *what did you hit?* and a child answers, *arm*, we can assume that the question was understood. But if the answer is *hit*, we can conclude that the child does not yet know the transformation relating Wh-forms to the underlying object of sentences. Some caution must be exercised in accepting appropriate answers at face value, since it is always possible that extralinguistic factors evoke an utterance that happens to be appropriate. Nonetheless, the method applies to any Wh-question, and has the virtue of involving a spontaneous linguistic performance. But only Wh-questions are within its reach, so it is hardly general, even though it

is not limited by language-environment correlations. A third study escapes some of these shortcomings.

Slobin and Welsh (1967) have used the simplest of methods for studying linguistic development—imitation. For reasons discussed later, children usually reformulate sentences given to them for imitation. Adult sentences too long to be retained in immediate memory are invariably altered to fit the child's grammar of the moment, which means that imitation can be used to study children's productive capacities, a fact known and utilized for some time (Menyuk, 1963, Lenneberg, Nichols and Rosenberger, 1964, Slobin, in press). For example, suppose that a child who is not yet inflecting verbs for the progressive aspect is asked to repeat *Adam's nose is dripping this morning*. If the entire sentence is beyond the child's capacity for immediate recall, the relevant part will tend to be imitated *nose drip*, not *nose dripping*. The model is reduced to the child's current grammar. Beyond the limits of immediate memory, a child produces in imitation only what he produces in spontaneous speech.

However, Slobin and Welsh have used imitation to study comprehension as well as production. In contrast to the use of imitation to study production, where the focus is on verbatim repetition, the focus in comprehension is on nonverbatim repetition combined with the preservation of meaning. When children reformulate a sentence in imitation, they express parts of the underlying structure of the model in a surface structure consistent with their own grammars. But when children fail to comprehend the model, they are unable to recover its deep structure. The imitation will then inevitably express a different meaning, or, more likely, no meaning at all. In this way—by noting whether or not reformulated imitation preserves meaning—comprehension can be studied.

The method can be (and has been) used with very young children, and can be applied to any aspect of the structure of sentences. Children can be induced to repeat what adults say, particularly if they are familiar with the investigator, and the sentences to be imitated are entirely a matter of the investigator's choice, so the method can be

used across the complete range of sentence types.

The following are a few of the examples given by Slobin and Welsh (1967). All are imitations by a 2½-year-old child. The first two are meaning-preserving, the last two are meaning-changing.

- | | |
|-------|---|
| Adult | Here is a brown brush and here is a comb |
| Child | Here's a brown brush an' a comb |
| Adult | John who cried came to my party |
| Child | John cried and he came to my party |
| Adult | The batman got burned and the big shoe is there |
| Child | Big shoe is here and big shoe is here |
| Adult | The boy the book hit was crying |
| Child | Boy the book was crying |

The first two imitations indicate an ability to comprehend but not produce certain grammatical forms, whereas the last two indicate a failure of comprehension. The second example is particularly interesting, since the child decomposed an embedded sentence into the matrix and constituent sentences underlying it. Slobin and Welsh's method deserves exploration, for it appears to have the virtues of generality and naturalness that the other methods for testing comprehension lack. Its main limitation is probably that children have to be well acquainted with the tester for the method to work. Slobin and Welsh's subject was very familiar with her tester, and may have been more willing than most young subjects to repeat incomprehensible sentences.

The Berkeley Cross-Cultural Project. Although not a method itself, except insofar as a program for investigating language acquisition in other cultures may be called a method, a group at the University of California (Berkeley) has compiled a manual of procedures (Slobin, 1967) for use in field studies of children and their language. In addition to the manual, the Project sends workers into remote places, pith helmet in hand, to observe children acquiring exotic languages.

Theories of Language Acquisition and Early Speech

Perhaps the most striking recent development in the study of language acquisition is

a resurgence of interest in theory. In an earlier period the explanation of linguistic development was a major goal. Entire books were devoted to the problem, for example, Stern and Stern (1907) and de Laguna (1927). But that was 40 or more years ago. Since then the field has been devoted to description, noteworthy as much for its indifference toward theory as for its sturdy accumulation of facts and figures. The entire literature has been excellently summarized in preceding editions of this *Manual*, and will not be much touched on here. We shall instead concentrate on the recent developments in theory and the empirical work asso-

ciated with them. The issues posed, both by theory and observation, are significant enough to warrant the devotion of space and attention.

Let us begin with a description of the speech of a 2-year-old. Not everyone has had the privilege of attempting to converse with such a person, at least not recently. The following examples, taken from records collected by Brown and Bellugi (1964), will set the tone. The first sample is from a 27-month-old child, the second from the same child at 35 months, and the third at 38 months. Vivid changes take place from sample to sample, a number of these will be discussed.

Child (28 months)

What dat somebody pencil

Floor

Where birdie go?

Birdie

Birdie up dere

Birdie

Read dat?

Read dat?

What inere?

Hammer

Hit hammer, mommy

No Cromer ———, mommy?

Hurt

Screw (did) happen

have screw

——no down there

table get broom

Yep, it fit

Yep, it fit

No fit

Put suitcase for?

What dat?

All right 'morrow

Yep

Use morrow, yep

Sure, use morrow

Adult

Whose pencils are they?

Floor?

Will you read it to me?

Is that a hammer, Adam?

Poor Adam. Did you hurt yourself? What happened, Adam?

Screw happened? You didn't even have a screw.

Does that one fit?

Does it fit?

What did you put it in the suitcase for?

That's tape. We'll use that one tomorrow.

Shall we use it tomorrow?

Child (35 months)

What his name?
 His name, Ursula?
 No I don't know his name
 I don't know
 Can't come up, fellah (to a yo-yo)
 Going pick pick up
 Lemme do again
 Don't don't hold with me
 Turning round
 It's stop
 What dat feeled like?
 What dat feeled like?

 I going drop my books
 (drops one book)
 An' what happens?
 I going drop it inne dump truck
 No please cry, cracker
 Cracker
 Please cry, cracker
 Yes

 Why not cracker can't talk?
 Romper domper tell me boo
 Romper domper tell me boo
 I got someping show you
 What's dat you have?
 Why me go?
 Why me going?
 D'you want brush him?
 D'you want he walk?
 Where's it?
 Why you rolling up?
 Hey, why why you waking me up?
 What you doing taking out?
 Why you knocking me off?

 Why not?
 I can't couldn't show it to her
 No

 I too big
 Dose are mines
 Dat's mines

Adult

His name
 I know his name

 Yes, it is turning around
 It stopped?

 It feels like rubber, I
 guess

 What?
 Please what?
 Please cry?
 How can a cracker cry?
 Crackers can't talk

 I'm not knocking you
 off

 You're going to show it
 to her?

Child (38 months)

Adult

like a racing car
 'you like some?
 broke my racing car

Oh, did you used to have one?

as
 ook at dat one

What part broke?

ike dis part broke
 is part broke, like that
 's got a flat tire
 /hat is dat?
 's a what?
 e his mouth is open
 /hat shall we shall have?
 /hy he going to have some seeds?
 /hy it's not working?

ou got some beads?

Yes

ist like me?
 got bead 'round myself
 it my knee

Hit *my* knee

it your knee
 /hat dat teacher will do?

/hy you pull out?

Dust in your hair

/ho put my dust on my hair?

Can you tell Ursula what
 the lesson is on the
 blackboard?

n the black which board?
 /e going see another one
 /e can read 'bout dis
 ou wanto read?
 /hat is dat?
 /hat is dat got?
 's got a flat tire
 /hen it's got flat tire, it's needs to
 go to the to the station
 he station will fix it
 ank come out through what?
 eally tank come out through here
 ommy don't let me buy some

/hat is dis?

That's a marble bag

marble bag for what?

For marbles
 It would be good to
 carry tiny cars

/hat is dat?
 an I keep dem?
 /hy I can keep dem?
 ow can I keep dem?
 /e don' do some games
 's broked?

At 28 months a child's speech often may seem random, some may uncharitably claim that it is not much improved at 38 months. Words appear to be thrown together haphazardly. The meanings often seem bizarre. But this is not so. Even the earliest word combinations are organized on definite principles, and the content is not bizarre but banal. In the following sections, we shall review the evidence for these claims and some possible explanations of them.

Telegraphic Speech Brown and Fraser (1963) have called the patterned speech of very young children "telegraphic." The expression aptly captures one characteristic feature of children's first multiple-word utterances: both in telegrams and in child speech, certain words are systematically eliminated. Looking at the sample collected at 28 months, we can see that articles, auxiliary verbs, copular verbs, and inflections of every sort are all missing: *put suitcase for? where birdie go? what innere? and yep, it fit*.

The telegraphic analogy is provocative and worth considering. Perhaps child speech is telegraphic for the same reason that real telegrams are—to save on costs. Just as a telegram-writer, in order to save currency, may delete the least informative words of a message while retaining content words and their order, a child may do the same to save space in memory. The fact that identical words, by and large, are eliminated in both situations adds some credence to the argument. But there are two difficulties with this account—one conceptual and one factual.

The factual problem is that children learning Russian also omit inflections from their early speech (Slobin, 1966b). Russian is a case-inflected language, and so conveys a great deal of information through certain inflections. Indeed, some of the information conveyed by word order in English is conveyed by inflections in Russian—the subject of a sentence, for example. Thus, in terms of informational importance, Russian children eliminate what American children retain, though both eliminate inflections. Clearly, it is not informativeness that counts.

The conceptual difficulty is that, although the least informative words of English tend not to appear in child speech, a lack of informativeness is itself a highly implausible explanation of this fact (Weksel, 1965). The

only way a child could know whether or not a word is informative without knowing its syntactic role in advance (a possibility excluded in this case) is by keeping records of the speech he has heard from his parents. Equipped with such records, he could discover which words are used with low frequency, and so are informative. But this is a vast actuarial undertaking—implausibly vast for a 2-year-old, whose exposure to speech is necessarily limited, and whose ability to keep unedited records must be small indeed.

Telegraphic speech is the outcome of the process of language acquisition. It is not the process itself. To understand it, we must penetrate more deeply into what children do.

Holophrastic Speech It is convenient to begin even before the period of telegraphic speech. "Holophrastic speech" refers to the possibility that the first single-word utterances of young children express complex ideas—that *ball* means not simply a spherical object of appropriate size, but that a child wants such an object, or that a child believes he has created such an object, or that someone is expected to look at such an object.

Many investigators of children's language (e.g., de Laguna, 1927, Stern and Stern, 1907, Leopold, 1949, McCarthy, 1954) have said that the single words of holophrastic speech are equivalent to the full sentences of adult grammar. It is true, of course, that adults typically require a full sentence to express the content of children's holophrastic speech. But this is not what is meant by the term "holophrastic." Rather, holophrastic speech means that children are limited phonologically to uttering single words at the beginning of language acquisition, even though they are capable of conceiving of something like full sentences. Let us look into this possibility, for it is central to understanding the course of events in later stages of language acquisition.

In what sense do children have in mind the content of a full sentence while uttering a single word? No one believes that children have detailed and differentiated ideas in the adult manner. On the contrary, everyone who has written on the earliest stages of language acquisition agrees that the conceptual side of holophrastic speech is undifferentiated and global. As Leopold (1949a) puts it, "the word has at first an ill-defined meaning and an ill-defined value: it refers to a nebulous

complex, factually and emotionally, only gradually do its factual and emotional components become clearer, resulting in lexical and syntactic discriminations" (p. 5)

A degree of semantic imprecision in holophrastic speech is therefore taken for granted. There remains, however, a question of what it is that children are imprecise about. Several factors seem to be important. Often children's single-word utterances are closely linked with action, sometimes so closely linked that action and speech appear fused. A child speaks both when he acts and when he wants action from others. Leopold's daughter, for example, said *walk* as she got out of a cart to walk, *away* as she pushed something away, and *blow* as she blew her nose (all at 20 months). Leopold (1949) calls these utterances self-imperatives to distinguish them from true imperatives, which are utterances apparently directed toward someone else. Of the true imperatives, *mit* from *komm mit*, *ma* from *come on*, and *away* from *put it away* are examples (also at 20 months). (Leopold's daughters grew up as German-English bilinguals.)

Besides such imperatives and self-imperatives, children's early speech often seems imbued with emotion. Indeed, Leopold believes that the first step in linguistic development occurs when a child attaches emotional significance to sounds produced accidentally while babbling. Meumann (1894) holds a similar view, believing that a child's first words express his "emotional relation" toward the objects and events referred to. This expressive aspect of children's speech maintains its dominating role for some time. According to Stern and Stern (1907, summarized briefly in English by Blumenthal, in press), the first word combinations of children consist of one part interjection and one part statement, the former continuing from the earliest stages of development 6 to 12 months before.

There is some consensus, then, that holophrastic speech is expressive of children's emotional states, as well as fused with action. There is a third characteristic sometimes claimed for holophrastic speech: it rests on an ability to name things. A child expresses his feelings about whatever is labeled in his utterance. The utterance [mam a], for example, seems to have meant for Leopold's daughter both "delicious!" and "food." The utterance apparently had both an expressive and refer-

ential component (It did not mean "mama" until 6 months later.)

Not every single-word utterance names something, however. Some utterances are purely expressive. Leopold's daughter said [dididi] in a loud voice to indicate disapproval and in a soft voice to indicate comfort. [dididi] was in fact an exclamatory call, much like the calls of apes, and was graded as these calls are from loud to soft. [dididi] was an articulated grunt. (See Marler, 1965, for examples of grading in the calls of rhesus monkeys.)

Examples of all these characteristics of holophrastic speech are included in Table 1, which is a list of the first seven "words" observed in the development of Leopold's daughter. Utterances marked with an asterisk were originally babbled sounds, the rest have recognizable sources in adult speech. The "words" of Table 1 are typical of the early one-word utterances recorded by others (Stern and Stern, 1907).

Various psychologists have at one time or another assumed that the truly linguistic utterances of children begin with labeling: a child learns the name of an object and says the name when the object appears before him (see Brown, 1958). However, it is far

Table 1 The First Seven "Words" in One Child's Linguistic Development

Utterance	Age (months)	Gloss
ʔəʔ*	8	An interjection. Also demonstrative, "addressed" to persons, distant objects, and "escaped toys"
dididi*	9	(loud) disapproval (soft) comfort
mam a	10	Refers to food vaguely. Also means "tastes good" and "hungry"
nenene*	10	scolding
tti*	10	used to call squirrels
pIti	10	Always used with a gesture, and always whispered. Seems to mean "Interested (-ing)"
de	10	An interjection. Also demonstrative. Used with the same gesture as above

After Leopold, 1949a

from clear that this interpretation is correct. The single-word utterances of children are ambiguous between naming and predication, no utterance can be both a name and predicate of the same thing. When a 1-year-old says *daddy*, he might be referring to that personage or he might be saying of that personage that he *is a daddy*. He cannot be doing both. We have here a fundamental fact of language acquisition.

Holophrastic Speech as Predication. The expressive and enactive aspects of holophrastic speech are best understood on nonlinguistic grounds, expressiveness is an example of the exclamatory function of primate communication in general (see Mailer and Hamilton, 1966), the fusion of speech with action is probably a consequence of the sensorimotor period in general cognitive development (Piaget, 1952). Here we consider a more special question, that holophrastic speech is not nominal, but rather is predicative. It is in this way that holophrastic speech corresponds to full sentences in adult speech.

De Laguna (1927) viewed the single-word utterances of children as predicates, comments made by a child on the situation in which he finds himself. The holophrastic word is the comment, together with the extralinguistic context, the topic of the comment, it forms a rudimentary kind of proposition, and thus amounts to a full sentence conceptually. It is worth quoting de Laguna's peroration in full.

It is precisely because the words of the child are so indefinite in meaning, that they can serve such a variety of uses, and it is also—although this sounds paradoxical—for the same reason, that they are fit to function as complete rudimentary sentences. A child's word does not designate an object *or* a property *or* an act, rather it signifies loosely and vaguely the object together with its interesting properties and the acts with which it is commonly associated in the life of the child. The emphasis may be now on one, now on another, of these aspects, according to the exigencies of the occasion on which it is used. Just because the terms of the child's language are in themselves so indefinite, it is left to the particular setting and context to determine the specific meaning for each occasion. In order to understand what the baby is saying

you must see what the baby is doing (1927, pp. 90-91, *italics in original*)

In Table 1 [mam a] is listed as meaning both "food" and "delicious!" But this is only its apparent meaning if we accept de Laguna's interpretation of early speech. With that interpretation, Leopold's daughter said [mam a] as a comment (is delicious) on an extralinguistic topic (food). The utterance is non-referential. Several other "words" in Table 1 can be interpreted in the same way—[ʔəʔ] and [de], and possibly [pIt], [nenene], and [tIt]. On the other hand, [dIdIdI] was not a comment at all (except in the trivial sense that "ouch!" is a comment on a pin prick), and [nenene] and [pIt] may not have been either.

If we accept de Laguna's interpretation of holophrastic speech, we suppose that purely nominal utterances play a marginal role in early stages of language acquisition. Except for those occasions when children's speech is purely expressive, it is invariably predicative. Children cry, or comment, and sometimes both. This remarkable fact of human communication has effects at every stage of linguistic development. One such stage is the following.

Pivot and Open Classes. The terms "pivot" and "open" are taken from Braine (1963a) and refer to the outcome of a distributional analysis of child speech. When such analyses are conducted of the speech collected from children of 18 months or so, at least two classes of words emerge. One class contains a small number of words, each of them frequently used—the "pivot" class. Words from the pivot class always appear in combination with words from the open class, and the class itself is slow to take in new members. The position of pivot-words in two-word sentences is fixed, first for some pivot classes and second for others, but never both for any particular pivot class. The "open" class contains the words not in the pivot class. There is typically a large number of open-words, which are therefore used infrequently in two-word sentences. The open class is quick to take in new members, and may stand alone in a child's speech. Given a two-word sentence the position of open-words is fixed with respect to the position of pivot-words. Open-words also appear in combination with each other, although

not necessarily in fixed relative positions

Such are the characteristics of the pivot-open distinction. The distinction can be summarized by setting down the combinations in which pivot- and open-words appear—the basic fact supporting the distinction in the first place. Using “P” and “O” for pivot and open, and assuming a child with a full complement of both classes, the following can occur

P + O
O + P
O + O
O

The only possibilities that never appear are pivot-words uttered alone or in combinations with each other. Everything else is possible.

Table 2 shows the pivot and open classes of three children studied by Brown and Bellugi (1964), Braine (1963a), and Miller and Er-

vin (1964), respectively. The table itself is from McNeill (1966a). For want of space, only a portion of each open class is represented, but the pivot classes are included in their entirety.

For the children in Table 2, sentences consisted of a word from the list on the left followed by a word from the list on the right—that is, P + O. Thus, *byebye fan*, *wet sock* and *that doed* all occurred. Not every combination allowed by Table 2 was actually observed, of course. But there are no evident differences between the combinations that did occur and those that did not, so it is assumed that the gaps arise from sampling, not grammatical restrictions.

What is to be made of the pivot-open distinction? Perhaps nothing at all. It is possible that the speech of young children arises through rote memory, as a simplified imitation

Table 2 Pivot and Open Classes from Three Studies of Child Language

Braine		Brown		Ervin
{ allgone byebye big more pretty my see night- night hi }	{ boy sock boat fan milk plane shoe vitamins hot Mommy Daddy . . . }	{ my that two a the big green poor wet dirty fresh pretty }	{ Adam Becky boot coat coffee knee man Mommy nut sock stool tinkertoy }	{ this that }
				{ the a }
				{ here there }
				{ arm baby dolly's pretty yellow come doed }
				{ other baby dolly's pretty yellow . . }
				{ arm baby dolly's pretty yellow }

From McNeill, 1966a.

of adult speech. If so, it would be a mistake to ascribe grammatical significance to what, in this case, would be an artifact of a distributional analysis. Before proceeding therefore we must first consider the possibility that the pivot and open classes do not mark the beginning of grammar in children.

There are several reasons for rejecting such a possibility. For one thing, if the sentences recorded from children are not produced but reproduced, the fact would reflect an astonishing ability to memorize verbal material. The number of *different* combinations recorded from one of Braine's (1963a) children in successive months was 14, 24, 54, 89, 350, 1400, 2500+. It is unlikely that the child was echoing 2500+ different combinations already heard.

Not only is it implausible that a great variety of forms in the speech of children could result from imitation, but in some cases it is impossible that their speech could be so derived. Take Braine's subject in Table 2, for example. He said such things as *allgone shoe*, *allgone vitamins*, and *allgone lettuce*—all apparently inventions of the corresponding adult models *the shoe is allgone*, *the vitamins are allgone*, *the lettuce is allgone*. Similar observations can be made of other children. Evin's subject said *that doed*, and Brown's, *big a truck*. Children do not hear English even remotely like this from their parents, but these examples correspond to a pivot-open pattern, and their occurrence reinforces a belief that the distinction reflects a genuine division of children's vocabulary into two classes.

The most compelling argument in behalf of the pivot-open distinction is the fact that pivot words never occur alone or in combination with each other. It is impossible to think of such a development as not reflecting a restriction on the use of words—that is, as not reflecting a grammatical system of some kind. In fact, the pivot-open distinction is a reflection of children's most primitive grammar. It is to a description of that grammar that we now turn.

Early Grammatical Rules The present section relies heavily on the work of Brown and his colleagues (Brown and Fraser, 1963, Bellugi and Brown, 1964, Brown, Cazden, and Bellugi, 1968). They have followed the linguistic development of three children, two girls and a boy, beginning in each case at

roughly 2 years and continuing for one child until age 5. The goal of Brown and his colleagues has been to describe the linguistic competence of these children at different points in development and to express the descriptions in the form of generative grammars. We shall first consider the results of their descriptive efforts, and then turn to a theoretical interpretation of them.

Not amazingly, grammars written for the earliest stages of development are simple in the extreme. The following rules summarize the performance of one child in Brown's study, Adam, at 28 months (after McNeill, 1966a).

$$S \rightarrow (NP) (VP) \quad (1)$$

$$NP \rightarrow (P) \left\{ \begin{matrix} N \\ N \ N \end{matrix} \right\} \quad (2)$$

$$VP \rightarrow V(NP) \quad (3)$$

Rules (1), (2), and (3) describe sentences of one to five words, the length depending on the options adopted in each rule. As usual, optional elements are enclosed within parentheses and alternatives within braces. The successive parentheses of Rule (1) mean that at least one element must be included in each sentence. Rules (1) and (2) apply to such sentences as *ball*, *that ball*, and *Adam ball*. N, PN, and NN. Rules (1), (2), and (3) apply to such sentences as *want ball*, *want that ball*, *Adam want ball*, and *want Adam ball*. VN, VP, NVN, and VNN. Rules (1) and (3) produce such sentences as *want* and *Adam want*. V and NV.

The combinations allowed by Rules (1), (2), and (3) did not occur in Adam's speech with equal frequency. For example, Rule (3) was employed more often than was Rule (2), sentences longer than three words were very rare, and two patterns (NNN and NPN) that should not have occurred at all according to these rules occurred 2% of the time.

All these characteristics and more are set forth in Table 3, which lists every combination of P, V, and N observed to occur in Adam's speech at the earliest stage for which observations exist, along with the frequency of occurrence of each combination. It is of course possible that a larger sample of Adam's speech would contain examples of other combinations, there is no way to judge such a possibility. However, as will be discussed

Table 3 Sentence Patterns that Correspond to Basic Grammatical Relations

Child's Speech		Corresponding Grammatical Relations
Pattern	Frequency	
P + N	23	modifier, head noun
N + N	115	modifier, head noun, subject, predicate
V + N	162	main verb, object
N + V	49	subject, predicate
Sum	349	
P + N + N	3	modifier, head noun
N + P + N	1	subject predicate, modifier, head noun
V + P + N	3	main verb, object, modifier, head noun
V + N + N	29	main verb, object, modifier, head noun
P + N + V	1	subject, predicate, modifier, head noun
N + N + V	1	subject, predicate, modifier, head noun
N + V + N	4	main verb, object, subject, predicate
N + N + N	7	subject, predicate, modifier, head noun
Sum	49	

From McNeill, 1966a

later, the combinations that did occur in Adam's speech possess a certain consistency, which the combinations that did not occur lack

Rules (1), (2), and (3) adhere closely to the superficial details of Adam's speech. They summarize the patterns in Table 3, but they do not necessarily describe Adam's linguistic competence exhaustively, and they may not represent it at all. It appears, for example, that phrases described by Rule (2) can have two different interpretations when a P is chosen for the first position. Sentences of this type strike an adult as being sometimes demonstrative (*that ball*) and sometimes modificational (*little ball*). If Adam was actually honoring such a distinction but not marking it in overt speech, Rule (1) would fail to reflect it. Adam in this case would in truth treat as different two constructions the Rule treats as the same. We shall return to this matter, there are a number of issues involved and it is convenient to discuss them in one place.

Rule (2) defines a particular grammatical constituent: it says that Adam possessed NPs at 28 months and that these consisted of an N, a PN combination, an NN combination, or a PNN combination. Rules (1) and (3) in turn contain NP as a subpart. What justification is there for ascribing such a superordinate constituent as NP to Adam? Could we not instead write several separate rules—one for N, one for PN, one for NN and one for PNN? Doing so would account for the same combinations of grammatical classes in Table 3, but would avoid claiming that Adam was acquainted with the abstract sentence constituent NP. However, there are several lines of evidence pointing toward the "reality" of NP in Adam's grammar, and hence supporting such definitions of NP as Rule (2).

Consider, first of all, some distributional facts. One is that single nouns and developed noun phrases appear in the same environments in children's speech (Brown and Belugi, 1964). For example,

Positions for Single N

that (flower)
where (ball) go?
Adam write (penguin)
(horsie) stop
put (hat) on

Positions for NP

that (a blue flower)
where (the puzzle) go?
doggie eat (the breakfast)
(a horsie) crying
put (the red hat) on

Apparently, wherever N can go NP can go, presumably because individual Ns are actually NPs

Another bit of evidence is that pauses in children's speech usually bracket NPs, not Ns "Put the red hat on" is a likely occurrence, whereas "put the red hat on" is not insofar as pauses reflect points of decision in speech (Goldman-Eisler, 1961), such utterances indicate that decisions are made in terms of NP and not N

Finally, consider the fact that the pronoun *it* is really a pro-noun phrase, since it replaces NP and not N. This is the case in the English of adults, and it is also the case in the English of children, as the following pairs reveal

Mommy get ladder	Mommy get <i>it</i>
Mommy get my ladder	Mommy get <i>it</i>

Adam sometimes combined both the pronoun and the NP the pronoun should have replaced in a single utterance, as in *Mommy get it ladder* and *Mommy get it my ladder*. That NP and N are treated alike, even in this case of deviation from adult English, is further evidence that NP is a genuine constituent

There are, then, grounds for assuming that NP is a superordinate constituent in children's early grammars. Except for sentences like *get it my ladder*, which were peculiar to Adam, all children provide evidence of the sort summarized above, NPs appear in the life of a child even before measles do

Rules (1), (2), and (3) describe Adam's sentences when he was 28 months old. At this point, his sentences were slightly less than two morphemes long on the average. Nine months later Adam's sentences have increased only slightly in length—to nearly three morphemes on the average—but his grammar has been much elaborated. Instead of three phrase-structural rules, the grammar now contains 14, instead of there being no transformational rules, the grammar now has two dozen. Table 4 presents the entire phrase-structural component and two rules from the transformational component of the grammar written for Adam's speech at 36 months. The sentences generated by this grammar are like those listed at the beginning of this section, all of which are taken from Adam's protocols at 35 and 38 months

Table 4 Part of the Grammar of a Child Thirty-Six Months Old

Complete-phrase structure rules

1. $S \rightarrow \left[\left[\begin{matrix} \text{Imp} \\ \text{Wh} \end{matrix} \right] \right] (\text{Neg}) \text{Nominal} - \text{Predicate}$
2. $\text{Predicate} \rightarrow \left\{ \begin{matrix} \text{MV} \\ \text{Cop} \end{matrix} \right\}$
3. $\text{MV} \rightarrow \text{Vb} (\text{Comp})$
4. $\text{Vb} \rightarrow (\text{Aux}) \text{V} (\text{Prt})$
5. $\text{Aux} \rightarrow \left\{ \begin{matrix} \text{Vc} \\ \text{B} + \text{ing} \\ \text{Past} \end{matrix} \right\}$
6. $\text{Comp} \rightarrow \left\{ \begin{matrix} \text{Adverb} \\ \text{Nominal} (\text{Adverb}) \end{matrix} \right\}$
7. $\text{Cop} \rightarrow \text{B} - \text{Pred}$
8. $\text{B} \rightarrow \left\{ \begin{matrix} \text{be} \\ \beta \end{matrix} \right\}$
9. $\text{Pred} \rightarrow \left\{ \begin{matrix} \text{Det} \\ \text{Nominal} \\ \text{Adverb} \end{matrix} \right\}$
10. $\text{Adverb} \rightarrow \left\{ \begin{matrix} \text{Locative} \\ \text{Adv} \\ \text{Prep Phrase} \end{matrix} \right\}$
11. $\text{Locative} \rightarrow \left\{ \begin{matrix} \text{somewhere} \\ \text{Adv} \\ \text{Prep Phrase} \end{matrix} \right\}$
12. $\text{Prep Phrase} \rightarrow \text{Preposition} \left\{ \begin{matrix} \text{Nominal} \\ \text{Adv} \end{matrix} \right\}$
13. $\text{Nominal} \rightarrow \text{some} \left\{ \begin{matrix} (\text{one}) \\ (\text{thing}) \end{matrix} \right\}$
14. $\text{NP} \rightarrow (\text{Det}) \text{N}$

Two transformation rules

T1 Wh incorporation for main-verb sentences

Wh Nominal Verb (Nominal) — some
 $\Delta \rightarrow \text{Wh} + \text{some } \Delta - \text{Nominal Verb (Nominal)}$

T2 Affixation of Past

$\text{X} - \text{Past} - \text{V} - \text{X} \rightarrow \text{X} - \text{V} + \text{Past X}$

Modified version of two tables in Brown, et al (1968)

The easiest way to convey an idea of how such sentences are described by the grammar in Table 4 is to provide a few examples, this is done in Figs 1 to 4. Before considering

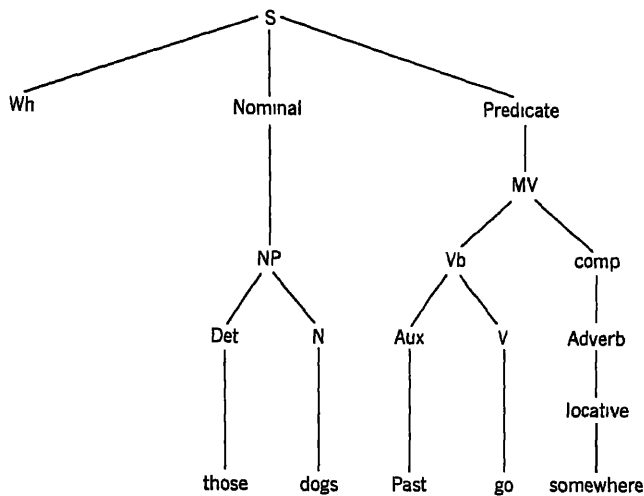

Fig 1 Deep structure of *where those dogs goed?* (from Brown, et al, 1968)

them, however, it is necessary to introduce certain notational conventions

Imp and *Wh* are grammatical markers, representing in the first case imperative sentences and in the second case such questions as *what*, *where*, and *who*. *Neg* stands for negation, *MV* for main verb, and *Cop* for copula (e.g., *is* in *the dog is an animal*). *Vc* is a "catenative" verb—*wanna*, *gonna*, and *hafta*. *Adverb* is a sentence constituent, like *NP*, whereas *Adv* is the grammatical category of adverbs proper. Because Adam sometimes produced sentences of the form *that my book* and sometimes of the form *that's my book*, a distinction is drawn between *be* and β ; *be* is a variant of the auxiliary verb, *to be*, β represents the same syntactic function but is never expressed in the superficial form of a sentence. *Det* stands for "determiner," a category including such words as *the*, *a*, *that*, *this*, *these*, and *those*. *Prt* stands for "particle"—the *up* in *look up*, and the *down* in *put down*. The symbol *some* Δ in the first transformational rule covers both *somewhere* (from phrase-structure rule 11) and *something* (from phrase-structure rule 13), both of which are grammatical markers, not words. The remaining symbols are defined by the grammar itself.

Consider now some of the sentences the grammar in Table 4 yields. The particular examples are *where those dogs goed*, *don't throw that ball*, *who jumping on me*, and *Susan is in the bath*. Four sentences, of course, do not exhaust the variety of grammatical forms

that Adam produced, but together they illustrate the workings of much of his grammar.

Figure 1 shows the deep structure of *where those dogs goed*, a well-formed question for Adam (from Brown et al, 1968). Of the 14 phrase-structure rules in Table 4, 10 are used to generate this phrase marker (rules 1, 2, 3, 4, 5, 6, 10, 11, 13, and 14), the two transformations listed at the bottom of the table relate the phrase marker to the surface structure of the sentence.

Figure 2 shows the deep structure of an

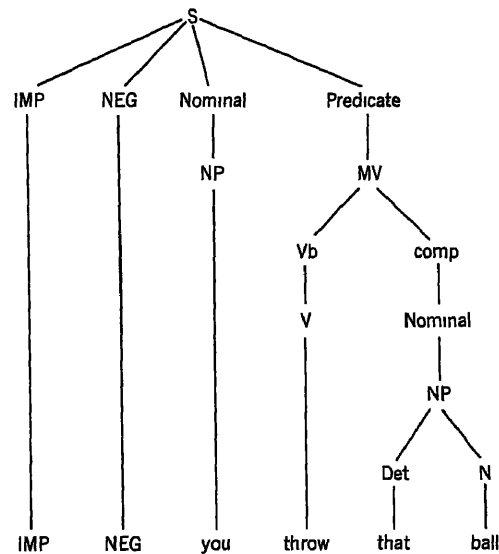

Fig 2 Deep structure of *don't throw that ball*

imperative sentence, *don't throw that ball*. Seven phrase-structure rules are involved, plus two transformations (not included in Table 4), one of which has the effect of deleting the subject of the sentence, *you*, and the other of introducing *do* and affixing it to *Neg*. The phrase-structure rules are 1, 2, 3, 4, 6, 13, and 14.

Who jumping on me, is a Wh-question, like the first sentence, but contains in addition a prepositional phrase and a verb in the progressive aspect, the auxiliary verb, *is*, has been omitted. Figure 3 is the deep structure generated by the grammar, a transformation parallel to T2 in Table 4 reverses the order of *ing* and *jump*, and a morphological rule changes *Wh-someone* to *who*. Because β and not *be* is the form of the auxiliary verb, the surface structure omits an auxiliary.

A final example is diagrammed in Fig. 4—the deep structure of *Susan is in the bath*. In this case, *be* is part of a copular not an auxiliary verb, so the affix-verb transformation required for *who jumping on me* does not apply. Phrase-structural rules 1, 2, 7, 8, 9,

10, 11, 12, 13, and 14 are used to generate this deep structure.

The grammar in Table 4 is not the complete grammar written for Adam at 36 months, and its omissions create two distortions the reader should be warned against. One distortion arises from the fact that only two of Adam's transformations are included in Table 4. Much of the complexity in the phrase-structural component, particularly in the development of the predicate, exists to support the transformations not in the table, omitting them naturally leaves a number of phrase-structural features undemonstrated.

A second distortion exists in the manner of introducing words into the deep structure. In Figs. 1 to 4 words—*Susan*, *on*, *jump*, etc.—are simply appended to the bottom of the phrase marker. Their relation to the remaining structure of the sentence is left unanalyzed. However, the grammar developed for Adam by Brown et al. goes farther. Each word in Adam's lexicon is represented as a set of syntactic features. The features state, in effect, the contexts each word can occupy,

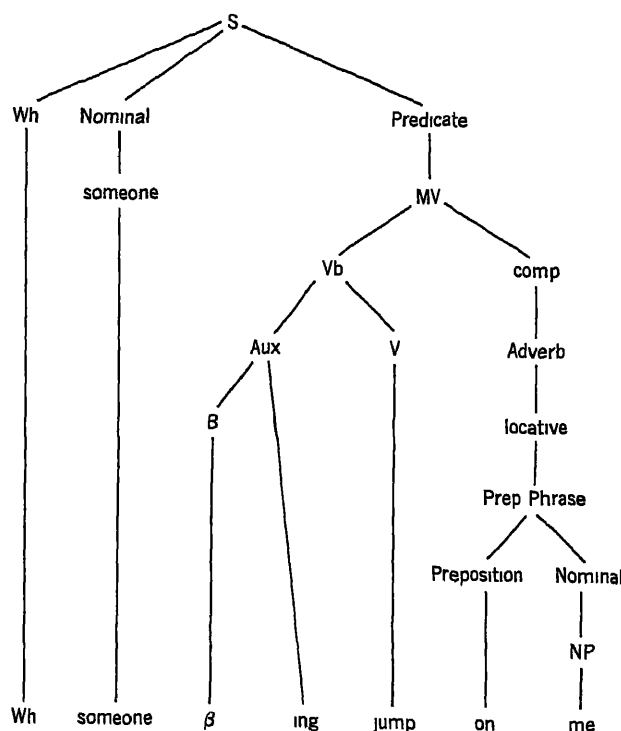

Fig. 3 Deep structure of *who jumping on me?*

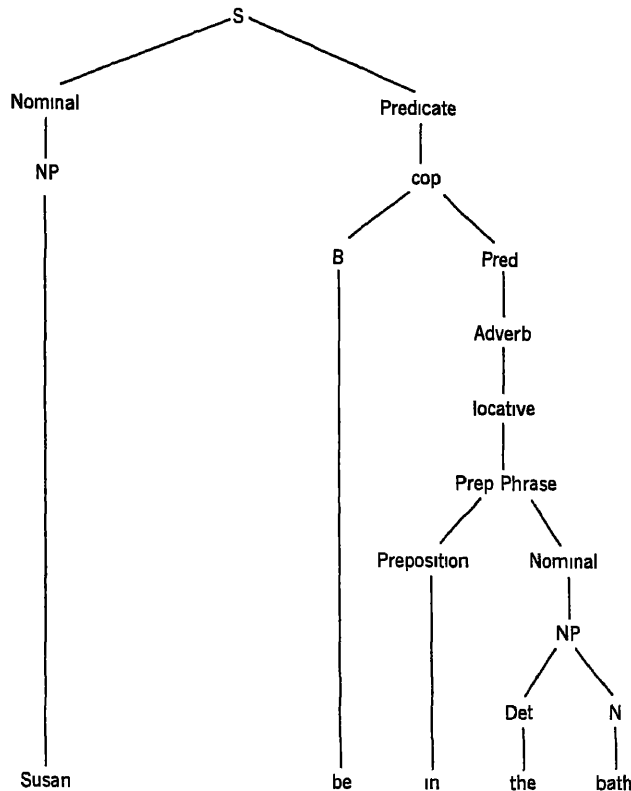

Fig 4 Deep structure of *Susan is in the bath*

plus the characteristics of each word as a context for other words. This can be done quite compactly. Take *dog*, for example. For Adam at 36 months, *dog* was a count noun, it could be pluralized, and it could follow determiners. The last feature states a context for *dog*, whereas the first two features state characteristics of *dog* when it is the context of something else. In formal notation, these properties of *dog* can be collected in the form of a lexical entry as follows:

$$\left[\begin{array}{l} +N \\ [+Det_] \\ +ct \\ \pm no \end{array} \right] \text{dog}$$

The $+N$ at the top signifies that *dog* belongs to the category of nouns. The $+ct$ indicates that *dog* belongs to the subcategory of count nouns—that it is a word like *table*, *man*, and *idea* and unlike *sand*, *mush*, and *justice*. The $\pm no$ indicates that *dog* belongs to the subcategory of nouns that can be either singular

or plural, and so is unlike such words as *pants*, *imagination*, and *John*. Finally, the $[+Det_]$ means that *dog* can follow determiners.

A rule of the grammar governs the insertion of words into phrase markers by requiring that all such phrase markers present the features specified in the word's lexical entry. Fig 1, for example, can receive *dog*—there is a slot of the right kind, this is also true for Figs 2 and 4. But Fig 3 has no place for *dog* or any other noun, for it accepts only pronouns in the two “nominal” positions.

When a lexicon is completely specified, it is possible to play items off against each other when inserting words into phrase markers. In this way the grammar can avoid describing bizarre combinations—such as *Where is in the dog*.

We have sketched briefly the development of the phrase-structural component of child grammar. We have seen that only a few rules are needed in the early stages to summarize

the sentences children produce—in the case of Adam, only three. A relatively short time later—9 months for Adam—many more rules are needed, a number of them possessing greater complexity than the few original rules.

Beside these changes, a child's grammar becomes elaborated through the introduction of transformations. None are included in the earliest grammars for children's speech, but 6 to 12 months later, 24 are used in the grammar written by Brown et al.

The grammar in Table 4, with a few small changes, serves for all the children studied by Brown, et al.

What do such developments tell us? The point has arrived where we must try to understand them. First to be discussed will be the rules of the phrase-structural component, then the transformational component will be considered. Many issues connected with the innate endowment of children for language arise with the first, and equally many issues connected with the linguistic experience of children arise with the second. All these matters will become clear as the discussion proceeds.

Contextual Generalization Braine (1963a) was the first to point out the distinction between pivot and open classes, and we shall begin with his account of the distinction and the view of language acquisition it entails.

Pivot words are so called because to Braine they are the only words for which a child knows the proper temporal location in a sentence—that they occur first, last, etc. Open words are used wherever pivot words are not, which means that in two-word sentences the positions of both pivot and open words are locked in place.

Various characteristics of the pivot-open distinction neatly follow from this simple account. Because at first a child knows the location of few words, pivot words are used with high frequency, and the class itself has few members. The pivot class increases in membership more slowly than the open class, presumably because it is more difficult to learn the positions of words than it is to learn new vocabulary regardless of position.

The main characteristic of the pivot-open distinction not accounted for by Braine's theory is the restriction on the use of pivot words—that they rarely appear alone or with other pivots. Why should such a restriction

exist if children learn only the positions of words in sentences? It is one thing to learn where to put a word in a sentence. It is something very different to learn to put it nowhere else or to put it only with open words. But the restriction on the use of pivot words carries most of the weight in justifying the grammatical relevance of the pivot-open distinction, an inability to account for it poses a fairly crucial problem.

Other objections have been leveled against Braine's hypothesis as well, but to present these issues we must first go into his argument in somewhat greater detail.

The actual mechanism of learning the position of words in sentences is left unspecified, although Braine has conducted a number of experiments purporting to demonstrate the existence of such a phenomenon (Braine, 1963b, but also see Bever, Fodor, and Wexsel, 1965a). Whatever the mechanism, it applies when children hear sentences and causes them to classify words according to the relative position the words occupy. For example, upon hearing *will you read it to me?* a child could observe that *you* is in the first half of the sentence, and that *read* is in the second half. Both words can then be so classified. Contextual generalization—the process by which this theory is generally known—carries *you* and *read* into new, analogous contexts.

Contextual generalization is not essentially different from ordinary stimulus or response generalization, except that it takes place across temporal positions. Its merit in the present context is that it serves to explain linguistic productivity. Having learned that *you* comes first in some sentences, contextual generalization places it first in other sentences. From *you read*, a child can produce *you come*, *you want*, *you sit*, *you bad*, and even *you all*. In short, *you* has become a pivot.

Two-word sentences grow to three-word sentences and beyond because a child observes the *relative* position of words. Having learned that *you* appears in the first half of some phrases, a child can later discover that these phrases appear in the first half of other more encompassing phrases. A child might learn, for example, that *you* is first in the phrase *you should*, and that this phrase is first in the sentence *you should come*. Contextual generalization again provides flexibility and

the child can produce *you can come, you should read*, etc

More important than an increase in length gained this way, there is also an increase in structural complexity. By learning that a word is first in a phrase, and that a phrase is first in a sentence, a child learns that sentences are hierarchically organized. It is ((*you should come*)). Thus positional learning, extended through contextual generalization, leads to the kind of sentence structure conventionally represented by a phrase-structural grammar. It is on this point that a rather loud dispute over Braine's theory has arisen.

The difficulty is that the order and arrangement of words in the surface structure of sentences is not necessarily the same as the order and arrangement of elements in the underlying structure (Bever, Fodor, and Wexler, 1965a, 1965b). Although it is only the underlying structure that contains information represented as a phrase-structure grammar, it is only the surface structure that is available for positional learning. The correct bracketing of the sentence above is (*you (should come)*). There is no guarantee that positional learning would arrive at this structure and not ((*you should come*)).

There is a dilemma here. The solution adopted by Braine (1965) is to restrict positional learning to simple declarative sentences, where the order of elements in the underlying and superficial structure is more or less the same. But this is to beg the question of syntactic learning. The cases where underlying and superficial structure are the same are among the things that a child must learn in acquiring language. The only way to avoid this difficulty, equally adopted by Braine (1965), is to change the syntactic analysis of sentences, by construing them all as having the same underlying and superficial structures. But this is to avoid the problem of language acquisition altogether (McNeill, 1968a). It is instead to do a novel kind of linguistics, asking what kind of language *could* be acquired through positional learning. Thus when faced with the alternatives of either begging the question of learning a transformational grammar or being irrelevant to it, it is evident that Braine's theory fails in a fundamental way to explain the acquisition of such grammatical systems.

There is a further difficulty. Braine (1963,

1965) considers transformations to be "sub-languages," each a specific way of deforming simple declarative sentences. Passive sentences, negative sentences, and the like, result. However, the resemblance of a sublanguage to a grammatical transformation is entirely superficial, dealing only with the manifest form of sentences. Whereas a transformation in linguistic theory is a relation between a deep and surface structure, a sublanguage is a relation between two surface structures. The difference between these views is discussed by Braine (1965) and Bever et al (1965a, 1965b, see also McNeill, 1968a, and Wexler, 1965).

If positional learning is not the way children develop knowledge of syntax, what then are we to make of the pivot-open distinction? Is it learned positionally, as Braine argues, only to lead nowhere—a syntactic cul-de-sac? If it is a cul-de-sac, it is one fallen into by virtually all children (according to Slobin, in press, a pivot-open distinction appears in the early stages of learning Russian, Bulgarian, Serbian, French, German, as well as English). This is a possibility. But there is another fact about these early grammatical classes, which suggests they are directly related to later syntactic development, at least for some children.

Differentiation and Generic Classification
Adam, one of Brown and Bellugi's (1964) subjects, developed the grammatical classes of adult English through differentiation. The class differentiated was a pivot class, the same one reproduced in Table 2, and the classes developed from it were articles, demonstrative pronouns, possessive pronouns, adjectives, and determiners. The entire process took place in 5 months, and followed the sequence diagrammed in Fig. 5.

Each step in Fig. 5 is the result of differentiating the pivot class then existing into one or more adult classes plus a new residual pivot class. The essential aspect of such differentiation is that entire adult classes are removed from an ancestral pivot class in one step—separate words do not straggle out at different times.

Zhenya, the son of the Russian linguist Gvozdev (1961), developed a pivot class equivalent to Adam's and formed adult grammatical categories through a comparable process of differentiation.

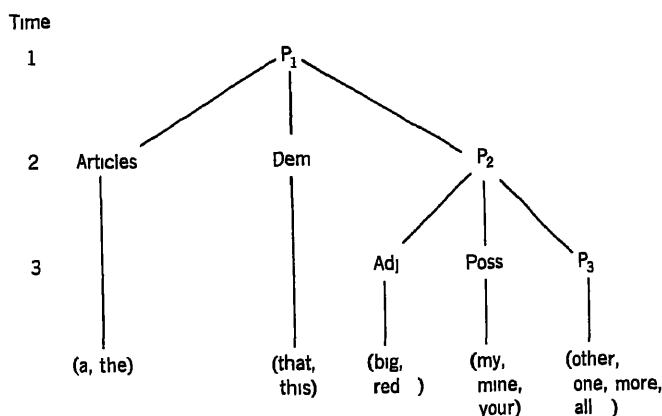

Fig 5 Differentiation of one child's pivot class (McNeill, 1966a)

It is the phenomenon of differentiation that suggests a direct relation between the pivot-open distinction and later syntactic developments. For differentiation can take place only if the classes differentiated—the pivot class in Adam's case—are *generically appropriate* (McNeill, 1966a).

A generically appropriate pivot class is one that ignores but potentially admits all the relevant distinctions of the adult grammar. Adam, for example, had the two articles in his pivot class at Time 1; he did not have one in the pivot class and one in the open class. Similarly, every adjective then in Adam's vocabulary was in the pivot class; there were none in the open class. In fact, Adam's pivot class contained every available member of several adult grammatical classes, even though none of these classes were themselves recognized in Adam's grammar.

Differentiation always presupposes generic classification—a fact not usually recognized. But generic classification is puzzling. For it means that children classify words (as pivot and open) in a way consistent with more subtle distinctions they are *yet* to draw, when differentiation takes place in the future. What guides children in such apparent teleology? The answer is by no means obvious or settled. Even to consider it, we must cover many of the recent observations made of children learning language.

Linguistic Capacities, Linguistic Universals, and the Problem of Abstraction. According to one traditional view, language is a systematic relation between expression and

content (see Appendix). In a transformational grammar such a view is embodied in the distinction between deep and surface structure: the deep structure of a sentence is associated with meaning and the surface structure with sound; deep and surface structures are in general different from each other but stand in a specific relation, which is explicitly described for every possible sentence by the transformations of the language.

One inherent aspect of each sentence therefore is the existence of an abstract deep structure. It is the phenomenon of abstraction, which all children face and overcome, that eliminates stimulus-response theory as a possible explanation of language acquisition. The difficulties with Brame's theory, discussed previously, derive from its commitment to this more general difficulty. The issues have been discussed in many places (Chomsky, 1959, 1965, Katz, 1966, Bever et al., 1965a, 1965b, McNeill 1966a, 1968a), as well as in the Appendix of this chapter, and need not be repeated here.

The phenomenon of linguistic abstraction presents a major theoretical challenge in the explanation of language acquisition. Fluent speakers somehow gain knowledge of the deep structure of sentences. They do so even though they never encounter such information in the form of examples, stimuli, or anything else. Moreover, children make use of information organized as deep structure very early in the acquisition of language. From the first moment of speech, indeed, children have the ability to communicate meaning, and do so

in a manner understandable to adults. It is easy to overlook what an astonishing fact this is. But it seems to mean that the most abstract part of language, its propositional content, is the first to develop. Children present evidence of employing something related to the deep structure of sentences *before* grammar is acquired.

Let us put the problem in a semiformal way, to help clarify some of the issues involved. Consider the "language acquisition device" discussed by Chomsky (1957, 1965), which we can call LAD for short (alternatively, a language acquisition system, or LAS—the feminine form). LAD receives a certain corpus of utterances. Some of these utterances are grammatical sentences in the language to which LAD is exposed, but besides grammatical sentences, the corpus also contains blunders, false starts, interruptions, and a certain amount of nonsense. The corpus may be large, but it is not unlimited in size. Assume that it contains the number of utterances overheard by a typical 2-year-old child.

Given such a corpus, LAD is so constructed that it can develop a theory of the regularities that underlie the speech to which it has been exposed. It can exclude the nongrammaticality in the corpus by constructing a theory about the regularities of the language. This theory is LAD's grammatical competence, its knowledge of the language behind the corpus. After developing such a grammatical theory, LAD becomes able to go far beyond the corpus with which it began. LAD can distinguish the infinitely many grammatical sentences in its language from the infinitely many nongrammatical alternatives, and it can judge how far from full grammaticality each of the latter deviates. The situation may be diagrammed as follows:

Clearly, the problem of understanding how LAD develops grammatical competence given a corpus requires understanding the internal structure of the box labeled LAD.

It seems useful to distinguish two major components of LAD. One is a set of *procedures* for operating on a corpus—for example, conducting a distributional analysis, or looking for transformations of certain kinds. The

other is a body of *linguistic information*—for example, that all sentences include noun and verb phrases, or that there *are* sentences, for that matter. It is conceivable that LAD is limited to just one of these components. LAD might contain a set of procedures for discovering a grammar or it might contain a set of assumptions about the form of grammar (McNeill, 1966b), or, of course, it might contain both (Fodor, 1966).

Whatever LAD contains, however, must be universally applicable. For LAD must be able to acquire any language; it cannot be biased toward some languages and away from others for reasons of internal structure. Thus LAD may contain information and procedures bearing on the general form of language but presumably contains nothing bearing on the form of any particular language to the exclusion of others. The following remarks are directed to the possibility that LAD contains universal linguistic information; almost nothing has been written on the possibility that LAD contains universal procedures of analysis.

The description of linguistic universals has already been alluded to. The theory of grammar—as opposed to the grammar of a single language—is a description of the general form of natural language (Chomsky, 1965, Katz, 1966). Its purpose is to state the conditions that grammars describing individual languages must meet. For example, grammars must all be transformational, and the base component must include rules stating the relations that hold among such syntactic categories as NP and N. When the grammar of a particular language represents the linguistic knowledge of the speakers of the language, and also conforms to the theory of grammar, one can claim to have *explained* the grammar of the language (Chomsky, 1965).

The argument becomes clear if we carry it a step further. Let us take the theory of grammar to be a description of LAD's internal structure. Whatever comprises the structure of LAD, is (or will be) described in the theory of grammar. The output of LAD—competence in a language—would then be explained by reference to the theory of grammar. A language has the particular grammar it does because the universal principles embodied in linguistic theory constrain the grammar that accounts for the corpus of sentences LAD has received. We thus have a hypothesis

about the internal structure of LAD it is described in the theory of grammar. It is an empirical question whether or not LAD can be so described.

LAD, of course, is a fiction. Our purpose in considering it is not to design an actual machine. On the contrary, our purpose is to isolate crucial aspects in the acquisition of language by real children, not by abstract ones. The purpose is served because LAD and children present the same problem.

LAD is faced with a corpus of utterances, some of them grammatical sentences and some not. So are children. From such a corpus, LAD develops a grammar on the basis of some kind of internal structure. So do children. Since children and LAD arrive at precisely the same grammar from precisely the same corpus, children and LAD must have precisely the same internal structure, at least within the limits that different children may be said to have the same structure. Accordingly, a hypothesis about LAD is *ipso facto* a hypothesis about children.

The proposed relation between the theory of grammar and children's innate linguistic capacities is simple and straightforward (e.g., McNeill, 1966b). Languages have all necessarily evolved to correspond to children's capacities. No language can evolve to be unlearnable. Because children automatically impose those features of language that reflect their capacities, such features appear universally. The theory of grammar thus becomes possible.

What are the universals mentioned in the theory of grammar, which we now presume to be a reflection of children's innate capacities? Some are phonological. Every language, for example, employs consonant and vowel types, syllabic structure, and not more than 15 distinctive features (Jakobson and Halle, 1956, Halle, 1964a). Other universals may be semantic—universals that are essentially constraints on possible concepts, on what is thinkable (Katz, 1966)—a fascinating possibility, which unfortunately cannot be discussed in these pages.

In the case of syntax, some universals describe characteristics of the deep structure of sentences (Chomsky, 1965). Every language utilizes the same basic syntactic categories, arranged in the same way—such categories as sentences, noun phrases, verb phrases. Every

language utilizes the same basic grammatical relations among these categories—such relations as subject and predicate of a sentence, verb and object of a verb phrase and modification within a noun phrase. Every language can recursively include sentences within sentences. And every language distinguishes deep and surface structure, and so is transformational.

The transformations of a language are mostly, though not exclusively idiosyncratic. However, the *types* of relation that exist between deep and surface structure are universal. For example, English relates the underlying and surface structure of auxiliary verbs by permuting the order of verbs and affixes (see Appendix). This transformation appears in English and French (Ruwet, 1966), and possibly elsewhere, but is not universal. However, the relation of permutation is universal. The transformational idiosyncrasy of each language arises from the way in which a few universal transformational types, such as permutation, are exploited.

We can put these several considerations from linguistic theory together into a hypothesis about language acquisition (McNeill, 1966b). Much of the deep structure of sentences is described by various syntactic universals, most transformations are idiosyncratic uses of universal types of relation. Making the assumption that such linguistic universals exist because of innate abilities, we can say that the abstractions of the deep structure are those universal categories and relations that reflect children's innate capacities, and they are *made* abstract when children discover the transformations of their language.

A language is thus acquired through discovering the relations that exist between the surface structure of its sentences and the universal aspects of the deep structure, the latter being a manifestation of children's own capacities. The interaction between children's innate capacities and their linguistic experience occurs at this point, in the acquisition of transformations—and it is here that parental speech must make its contribution. (A similar argument is given by Schlesinger, *in press*.)

Predication and the Basic Grammatical Relations If a language is acquired through discovering the transformations that relate surface structures to the universal aspects of

the deep structure of sentences, then these universal aspects must be present in children's earliest speech, at least, they must logically be present before the transformations that depend on them are acquired. An aspect of children's capacities will not appear until it has "matured," but everything in earliest speech that is not transformational should reflect an aspect of children's capacities. The early linguistic constructions of children should therefore be the universal parts of the deep structure of sentences but, in effect, pronounced directly. It is for this reason that children are able to express meaning from the onset of language acquisition.

Recall the phenomenon of holophrastic speech. Such speech consists of single-word utterances that have the conceptual content of full sentences. De Laguna (1927) argued that holophrastic utterances have such content because they are comments on aspects of the situation in which the speech occurs. If we accept de Laguna's argument, the phenomenon of holophrastic speech can be seen as the most primitive manifestation of a basic grammatical relation, predication, and therefore as a very early appearance of what ultimately becomes part of the deep structure of sentences. Children's speech is understandable by adults even in its most primitive form because it makes use of predication, and predication is a fundamental aspect of the deep structure of sentences.

De Laguna believed that two-word sentences emerge when children label the topics of their comments. She was interested in this step because it liberates the interpretability of child speech from an extreme dependence on nonlinguistic context. She was little concerned with the extension of grammar beyond that. Nevertheless it is clear that her views encompass the early phases of patterned speech in general.

The basic grammatical relations correspond to the traditional grammatical functions of subject, predicate, verb, object, modifier, and head. Such relations hold among the syntactic categories of the deep structure, they are universal, and they are honored in the early speech of children.

Table 3, presented in the preceding section, contained every combination of Adam's grammatical classes observed in his speech at 28 months. It was remarked at that point that

the combinations of grammatical classes observed in Adam's speech possess a certain consistency that the combinations not observed in his speech lack. We can now see what the consistency is.

The combinations in Table 3 are the patterns of Adam's grammatical classes that result from a mechanical application of the definitions of the basic grammatical relations as contained in linguistic theory (McNeill, 1966a). A predicate, for example, is defined in linguistic theory as a VP directly dominated by S. For Adam, the following combinations are consistent with this definition: VN, NV, VNN, VPN, NVN, NNV, and NPN (the last assuming an absent V—the sentence was *Adam two boot*). The other relations can be defined in a similar way. A subject is an NP immediately dominated by S, a main verb is a V immediately dominated by VP, an object of a verb is an NP immediately dominated by VP, a modifier is a determiner (Det) immediately dominated by NP, and a "head" is an N immediately dominated by NP. Opposite each combination in Table 3 are listed the basic grammatical relations with which it could be consistent. As the reader can see, every combination of grammatical classes Adam did produce is consistent with at least one basic grammatical relation, and most of the combinations Adam did not produce are not consistent with any basic grammatical relation. (Kelley, 1967, points out that two combinations, consistent with the basic grammatical relations, did not occur in Adam's speech.) With three grammatical classes, there are $(3)^2 = 9$ different patterns two-words long and $(3)^3 = 27$ different patterns three-words long. Five of the two-word patterns and 17 of the three-word patterns do not correspond to the basic grammatical relations, none of them occurred in the sample of utterances collected from Adam at 28 months.

One explanation of Table 3 therefore is that Adam organized utterances in terms of the basic grammatical relations, but he had not yet acquired any of the transformations in English that combine structures or add elements—for example, conjunctions, complements, or embeddings. It is for this reason that patterns such as VVN did not occur in his speech, even though such sentences correspond to common surface structures in the

speech of adults—for example, *come and eat lunch*. Indeed, many of the patterns excluded from Adam's speech correspond to patterns available in the surface structure of adult sentences.

We can relate Table 3 to de Laguna's argument about predication. If we search Table 3 for patterns that could express predication, we find that in one way or another every pattern except PN (*another ball*) and PNN (*big Daddy book*) could do so (and even some of these sentences probably are predicative—*that Becky*, for example, or *that Becky ball*). In terms of frequency of occurrence, between 70 and 90% of Adam's utterances express predication (the lower figure excludes all potential modificational combinations, the higher figure includes them). If predication is a primitive form of semantic organization, as de Laguna claimed, most early utterances of children should express it, and such is the case with Adam. In contrast, only four patterns (PN, NN, NNN, and PNN in Table 3) could conceivably be subjects without predicates. All other instances of NP occur in the context of the object or predicate relations.

If now we look in Table 3 for patterns that could be predicates with subjects and patterns that could be predicates without subjects, we find a preponderance of the latter. The patterns that correspond to predicates without subjects are VN (*change diaper*), VPN (*hit my ball*), and VNN (*read Cromer paper*)—none of which was judged to be imperative, there were 194 such utterances at 28 months. The patterns that correspond to predicates with subjects are NN (*Joshua home*—meaning "Joshua is at home"), NV (*daddy go?*), NPN (*Adam two boot*), PNV (*another doggie run*), NNV (*Adam mommy stand*), NVN (*Adam change diaper*), and possibly NNN (*Adam mommy pencil*), there were 178 such utterances at 28 months.

Even though there is a greater variety of predicates with subjects, there is more frequent use of predicates without subjects. The divergence becomes more pronounced when we look for the single most frequent two- and three-word patterns. In both cases they are predicates without subjects—VN and VNN—and they are more frequent by a large margin (Table 3). Such a relation with frequency would result if the sentences with subjects were all recent acquisitions and the sentences

without subjects had existed in Adam's repertoire for some time. Gruber (1967) draws a similar conclusion for the speech of another child. There is therefore some support for de Laguna's contention that children first produce isolated predicates and later add subjects.

Predication, however, is not the only relation evident in the speech of children at this early stage. In addition, children express direct and indirect objects, modification, and possibly other relations. Among Adam's utterances, for example, were *see truck*, *write paper*, and *dirty paper*—a direct object, an indirect object, and a modificational construction, respectively. He also uttered apparent possessives—for example, *Adam hat*—which is a variety of modification, according to recent views (Chomsky, 1967).

All these examples manifest different grammatical relations, and a question arises concerning their origin. It is impossible to say from Adam's evidence whether or not these relations had equal tenure in his grammar at 28 months. All four conceivably existed at the holophrastic stage. But it is equally possible that originally Adam's utterances expressed only predication, to which was first added modification (including possessives), then direct objects of verbs, then subjects, and finally indirect objects of verbs—this being the order of the frequency of these relations in Adam's speech at 28 months.

Whatever the order of emergence of such relations, however, it is difficult to imagine that they were, in any sense, discovered by Adam. For example, Adam apparently expressed the object of a preposition before he included prepositions in his speech, as in *write paper* and several other examples. It is difficult to see how he could have discovered such a relation from surface structures without also discovering the preposition. The preposition is the only feature on the surface that identifies the relation. It seems rather that Adam used the different basic grammatical relations, as they became available, to organize his other linguistic experiences—for example, acquisition of such prepositional phrases as *write on the paper*.

Other children also manifest these relations. A child studied by Gruber (1967) has already been mentioned. The two other children followed by Brown and his collaborators give parallel evidence. Perhaps more striking is the

appearance of these relations in the speech of children exposed to other languages. Evidence for Japanese children has been discussed by McNeill (1966b). Slobin (in press) has reviewed a number of diary studies and found evidence for the early emergence of the basic grammatical relations in Russian, Serbian, French, German, Georgian, Italian, and Bulgarian.

Intrinsic and Extrinsic Predication² Adam's sentences without subjects at 28 months often made reference to himself as the omitted but implied subject. *Change diaper* meant that Adam wanted to change his diaper, *hit my ball* meant that Adam was claiming this act for himself, *read Cromer paper* described something that Adam was doing. His sentences with subjects, on the other hand, almost always had an NP other than *Adam* or *I* as the subject—*Joshua, daddy, another doggie*, etc.

The pattern of omitting *Adam* and *I* from the subject position of sentences reflects a distinction between two types of predicative relation available to children, between what we may call *intrinsic* and *extrinsic* predication. The distinction is widespread. It appears as a conditioning factor for the presence of subjects in children's sentences; it appears as a permanent distinction in the Negro dialect of English (as between *he working* and *he be working*, Labov, Cohen, and Robins, 1965), and it controls two transformations in Japanese.

Adult speakers tend to omit the subjects of sentences when it is clear that the subject will be understood by a listener. To use Vygotsky's (1962) example, one would not say "the bus for which we have been waiting so long is here at last", one would simply say "at last". Adam apparently believed that sentences involving himself as the subject were clear in this sense, whereas sentences containing other NPs were not.

How did he arrive at such a conclusion? The egocentrism of young children comes to mind as a possible explanation, but in fact it does not provide an answer. For if Adam was egocentric in the sense of Piaget (1926), we must wonder why he ever included subjects in sentences; all subjects would appear to

be "understood" to an egocentric mind. Egocentrism plays a role in Adam's speech, but it is secondary to the more fundamental role of intrinsic and extrinsic predication.

Let us turn to the acquisition of Japanese. It is here that the distinction between extrinsic and intrinsic predication is most clearly revealed; then we can return to the acquisition of English.

Japanese, like many languages, uses postpositions. Two of them are reserved for marking the superficial manifestation of the subject of a sentence. The two postpositions have nearly identical distributions in the surface structure of sentences, in that they can replace one another, but they have different implications for the underlying structure. One postposition, *wa*, is used when the relation between the subject and predicate of a sentence is of an intrinsic type, the other, *ga*, is used when this relation is of an extrinsic type.

The distinction between intrinsic and extrinsic predication may be cognitive in origin (and thus fall in the domain of "cognition and language"), and all languages may therefore exploit it, although in different ways. In Japanese the two types of predication resolve themselves into a distinction between the subject (*ga*) and topic (*wa*) of sentences; this distinction is a special syntactic point and need not concern us here.

Sentences requiring the postposition *wa* in Japanese have predicates that state an intrinsic property of the subject. It is felt intrinsicness that counts, no difficult ontological insights are required of a Japanese speaker. Habitual activities, for example, are regarded as intrinsic—*daddy works in an office*. So is attribution—*government architecture is grotesque*, membership in a hierarchy—*a collie is a dog*, definition—*that is a collie*, and various truisms such as *all men are mortal*.

Sentences with *ga* have predicates that state extrinsic properties of the subject. Such sentences often take the form of momentary description—*there is a dog in the yard* (when this is not customary). As with an intrinsic predicate, the information contained in an extrinsic predicate is asserted about a subject, but unlike an intrinsic predicate such information is not felt to be an inherent part of the subject.

How are *wa* and *ga* acquired? Both postpositions are introduced into the surface struc-

² The discussion in this section has been developed jointly with Nobuko B. McNeill.

ture of sentences by transformations (Kuroda, 1965) and at first do not appear in the speech of children. At 28 months or so (in the children studied by McNeill, 1966b), *ga* first comes to be used, although not frequently. When used, however, it is used appropriately—always with extrinsic predicates. About 6 months later *wa* first appears, and it too is always used appropriately—with intrinsic predicates. Thus extrinsic predication appears to develop before intrinsic predication.

However, we have only half the story, and the second half reverses the interpretation of the first. It is possible for a native speaker of Japanese to classify children's utterances containing neither *wa* nor *ga* according to the postposition required. McNeill (1968b) found that approximately 90% of Japanese children's sentences are sufficiently clear to be so classified. The results of this procedure are clear: the great majority of children's early sentences consist of intrinsic predicates. Although *ga* is the first postposition to be included in child speech, *wa* is the postposition most often called for.

We have what appears to be a paradox. On the evidence of the postposition first acquired, extrinsic predication is dominant, but on the evidence provided by direct judgments of children's predicates, intrinsic predication is dominant.

The paradox is resolved when we observe

the effect of the two types of predication on the inclusion of subject-NPs in sentences. If one looks at whether a child utters an isolated predicate or a predicate with a subject, one finds that subjects are usually included with extrinsic predicates and are usually omitted with intrinsic predicates. The transformation for *wa* cannot be formulated if there is no superficial NP to which the postposition can be attached. The situation is the opposite with extrinsic predication. Subjects are usually included with such predicates, so the transformation that introduces *ga* can be, and is, formulated early.

The same tendency exists in the speech of English-speaking children. English-speaking children, of course, also do not include *wa* or *ga* in their early speech. They therefore present a situation comparable to the speech of young Japanese children, and a native (but bilingual) speaker of Japanese can also classify their sentences according to whether they "require" *wa* or *ga*. The procedure leads to the same outcome (McNeill, 1968b). There is a strong tendency for the children studied by Brown and his colleagues to include subjects with extrinsic predicates and to omit subjects with intrinsic predicates.

The following are examples of the two types of predication from four children—two English-speaking and two Japanese-speaking

Eve

- (extrinsic) Mommy sit bottom
Fraser read Lassie
- (intrinsic) on Wednesday (the stock answer to "When's Cromer coming?")
on my head (said of a hairband)

Adam

- (extrinsic) Bunny rabbit running
Cromer right dere
- (intrinsic) pretty, Mommy?
go dere, Mommy? (said of a puzzle piece)

Izanami

- (extrinsic) Reiko said "no"
tape goes round and round
- (intrinsic) the same (said of two dresses)
office (said of her father)

Murasaki

- (extrinsic) the lion's mommy is seated
a giraffe is eating grass
- (intrinsic) can't eat the rind (said of an orange)
delicious (said of a cracker)

We can now see why Adam tended to omit mentioning himself as the subject of sentences. The predicates of such sentences were intrinsic. An intrinsic predicate is one that entails its subject, the information contained in the predicate is felt to be inherent in the subject, which therefore need not be mentioned. Possibly Adam egocentrically felt that anything predicated about himself was intrinsically true. Other NPs, when serving as the subjects of sentences, were or were not included precisely according to whether or not the predicate was felt not to be intrinsically true of the NP.

It is possible that holophrastic utterances consist largely if not exclusively of intrinsic predicates. That would be one reason for a limitation of such utterances to single words and for a dependence of holophrastic speech on context. Children would add subjects to predicates, as de Laguna believed, when the predicates become extrinsic. Such an event appears to happen first when children are 18 to 24 months old. It is as if one suddenly realized that he was talking to a blind man when he said "at last" as a bus appeared around a distant corner.

The Differentiation of Grammatical Categories. Figure 5 traced the history of the pivot class of one child, Adam. According to Slobin (in press), Gvordzev's son Zhenya had a pivot class almost identical to Adam's: both children included demonstrative and personal pronouns, various adjectives, and such determiners as *other*. Presumably the two children passed through a similar series of steps in reaching the grammatical classes of their languages.

The interpretation made before of Adam's pivot class can also be made of Zhenya's pivot class, although exposed to a different language. Zhenya as well as Adam arrived at a generically appropriate classification of the words in his vocabulary; indeed, Adam and Zhenya arrived at the same classification. Now, after having reviewed evidence for the existence of children's innate linguistic abilities, in particular the ability to organize sentences according to the basic grammatical relations, we can return to the problem of generic classification.

The reader will recall the problem a generically appropriate pivot class honors distinctions in adult grammar that children have

not yet drawn. Both Adam and Zhenya, for example, placed all adjectives into a pivot class even though adjectives themselves were not yet recognized as a grammatical class. The problem is to explain such apparent teleology.

Two accounts come to mind. Each corresponds to a different conception of grammatical classes in linguistic theory. In the end, we shall find a way to put the two explanations together, but to begin with we shall present them as if they were alternative accounts.

One explanation was proposed by McNeill (1966a). The argument in this case relates the telegraphic sentences of young children to the semigrammatical sentences of adults. A speaker of English will recognize *John plays golf*, for example, as being well-formed. He will also recognize *golf plays John* as being semigrammatical, a deviation from the grammar of English, and *golf plays symmetrical* as being even less grammatical than *golf plays John*. Moreover, speakers of English can interpret semigrammatical sentences. *Golf plays John* is a devastating remark in part because it is deviant and in part because it is analogous with the well-formed *John plays golf*.

There are two salient facts in connection with the phenomenon of semigrammaticality. One is that semigrammatical sentences are ordered according to how far they depart from being well-formed. The other is that fluent speakers have an ability to interpret semigrammatical sentences, even though they are not well-formed.

Chomsky (1961), who raised this problem, gave an explanation of it in terms of a postulated hierarchy of grammatical categories. Such a hierarchy has never actually been established, but one can imagine what some of its properties would be. Every level of the hierarchy would encompass the total lexicon of English. The lowest level would comprise all the grammatical classes of English, the next level would include the same words except that certain distinctions are lost, the level above this would include again the same words except that even more distinctions are lost, and so on until the top-most level, which would consist of one gigantic grammatical class. The actual number of words, of course, is irrelevant. Chomsky's hierarchy could be

established within the much smaller vocabulary of children

A semigrammatical sentence is one that can be represented by the rules of the grammar only at some intermediate level in the hierarchy of categories. Of two semigrammatical sentences, the one that deviates most from being completely well-formed is the one that is represented at a higher level in the hierarchy of categories. *John plays golf* is represented by the rules of the grammar at all levels of the hierarchy, including the most differentiated level at the bottom. However, *golf plays John* can be represented only down to the level where the distinction between animate and inanimate nouns is lost, and *golf plays symmetrical* cannot be represented below the level where the distinction between nouns and adjectives—two major grammatical categories—is lost.

Understanding a semigrammatical sentence depends on noting an analogy with well-formed sentences represented in the same way as the semigrammatical sentence at the appropriate level in the hierarchy. Thus *golf plays John* is perceived as analogous to *John plays golf* because both receive the same representation when the distinction between animate and inanimate nouns is abolished.

McNeill's (1966a) suggestion was that children's sentences are semigrammatical in this technical sense. Like *golf plays John* and *golf plays symmetrical*, the telegraphic sentences of children omit certain grammatical distinctions. Moreover, it was claimed that the differentiation of the grammatical classes shown in Fig 5 is in fact a record of Adam's progress down the hierarchy of categories Chomsky discussed. Thus early sentences from children honor fewer distinctions than later sentences do, just as semigrammatical sentences honor fewer distinctions than well-formed sentences do, and the distinctions children draw at any time are generically related to the distinctions they draw at later times, just as the category of nouns (for example) is generically related to the categories of animate and inanimate nouns.

Children's sentences are therefore understood by adults as semigrammatical sentences. Since the information is the same, adults understand such infantile utterances as *that a Adam ball* through the same mechanisms they use to understand such semigrammatical sen-

tences as *golf plays John*. In both cases, grammatical distinctions of English are violated, thus placing the sentences on an intermediate level in the hierarchy of categories and the sentences are understood on the basis of analogies with well-formed sentences.

An experiment reported by McNeill (1966a) lends support to this identification of child sentences with semigrammatical sentences. Pairs of sentences recorded from children at different ages were given (in written form) to adults, who had to decide which member of each pair had been uttered by a younger child. Vocabulary and length were matched within pairs, every sentence was grammatically deviant, only the age of recording and, presumably, the degree of grammaticality differed. Adults could accurately pick the earlier sentence 81% of the time (chance being 50%), earlier sentences thus tend to be more deviant when judged against the standards available to adults. Unless adults have special standards for judging child speech, it seems clear that there is a basic similarity between the phenomenon of semigrammaticality in adults and the linguistic development of children.

The suggestion in McNeill (1966a) was that the upper levels of the hierarchy of categories are universal among languages and are a reflection of one aspect of children's innate linguistic abilities. It is certainly difficult to imagine that children learn such generically appropriate categories. There is no class of "modifiers" in English or Russian that corresponds to Adam's and Zhenya's pivot class. However, children may be equipped to notice a general function of modification when it exists in the speech of adults, and to place words together when they serve this function. At some (fairly high) level in Chomsky's hierarchy, articles, demonstrative and personal pronouns, adjectives, and such determiners as *other* are all alike. Adam and Zhenya, if they had available such a level in the hierarchy, would treat these different adult classes as the same, that is, as pivots. Discovery of the adult categories could then proceed, as it did, by differentiation.

Such is one account of children's early syntactic organization. It makes a strong prediction, which can easily be examined. If children initially classify words according to a universal hierarchy of categories, then all

primitive grammatical classes must be generically appropriate. Children must never place words from the same adult class into different grammatical classes of their own.

In fact some children do not arrive at a generically appropriate classification of words. One of Miller and Ervin's (1964) subjects, for example, placed adult adjectives in both the pivot and open classes. Izanami, one of McNeill's (1966c) subjects, did the same. The early grammatical classes of these children were not generically appropriate and could not possibly be refined through differentiation.

There is a difficulty then. The problem appears to lie with the original analysis of adult syntactic classification, and not with the extension of such an adult analysis to the syntactic classification of children. On independent grounds, Chomsky (1965) rejected the notion of grammatical categories, replacing it with the concept of syntactic features. The change in theory was made to take into account the cross-classification of words. Consider, for example, the four nouns, *John*, *elephant*, *ocean*, and *Egypt*. Two are proper nouns (*John* and *Egypt*) and two are common nouns (*elephant* and *ocean*). One might suppose that English contains these two grammatical categories. But the four words present a second distinction, which cuts across the first. *John* and *elephant* also are animate nouns, and *Egypt* and *ocean* are inanimate nouns. Logically no way exists to make one of these distinctions hierarchically superior to the other. Inanimate nouns, for example, are not all proper nouns, nor are they all common nouns. They may be either, for nouns are cross-classified.

A consideration of such facts led Chomsky to do away with the idea of a grammatical category, and to replace it with the idea of a syntactic feature. Thus *Egypt* has the features [inanimate] and [proper], *John* has the features [animate] and [proper], etc.

It is not surprising therefore to find that children also cross-classify grammatical classes. Words in the same adult "class" can have in part different features. Depending on which features a child uses, words from the same "class" may find their way into different categories in the child's grammar. Suppose, for example, that at an early point in development a child classifies words encountered in

adult speech according to whether they are [animate] or [inanimate], but in no other way. Then *elephant* and *ocean*, two nouns, would appear in different syntactic categories, as would *Egypt* and *John*. Miller and Ervin's and McNeill's subjects apparently cross-classified adjectives in a way comparable to such cross-classification of nouns.

If we accept the possibility that children classify words according to features, then how can we explain such generically appropriate classification as does occur? What led Adam and Zhenya to treat demonstrative and personal pronouns, articles, determiners, and adjectives alike?

In the view sketched above, generic classification can mean only one thing. At the time Adam's and Zhenya's speech was observed, they were classifying words according to a single feature. The feature must have been one shared by the various words classified together as pivots, these words, as they were encountered in adult speech, were then placed into the pivot "class."

The function played by Adam's and Zhenya's pivot words was modification, indeed, Brown and Bellugi (1964) referred to Adam's pivot class as a modifier class. We therefore might suspect that the pivot class and the feature on which it is based are associated in some way with the basic grammatical relation of modification. As mentioned previously a relation of modification holds between a determiner and a noun when both belong to the same NP. In order for this definition to hold, any word understood to modify a noun must be classified [+Det] and [+—N], similarly, any word understood to be modified by a determiner must be classified [+N] and [Det—]. That is, the grammatical relation of modification automatically imposes two grammatical categories, Det and N, and establishes a contextual relation between them—N and Det—, respectively. Evidence has already been presented that the basic grammatical relations are reflected in children's earliest linguistic performances. A child able to recognize that two words are related as modifier and modified is also able to classify one as [+Det, +—N] and the other as [+N, +Det—]. Doing so is an automatic result of understanding the basic grammatical relation. The second set of features designates a class of nouns. The

first set exactly designates the pivot class of Adam and Zhenya

This argument can be generalized to cover each of the basic grammatical relations. If the reader will visualize a tree-diagram representing the deep structure of a simple declarative sentence (or look at Table 10 in the Appendix), he will see that each of the six following sets of features can be derived from the basic grammatical relations (asterisks will be explained below)

predicate	[+ VP, + NP—]*
subject	[+ NP, + —VP]
main verb	[+ V, + —NP]*
object	[+ NP, + V—]
modifier	[+ Det, + —N]*
head	[+ N, + Det—]

The basic grammatical relation responsible for each set is indicated on the left (The use of + NP and + VP as features has been proposed for adult grammar by Chomsky, 1967)

It is important to note that these features are automatically made available whenever a child obtains *any* meaning from adult speech. Not everything in adult speech is necessarily understood, of course, but everything understood is necessarily classified according to the preceding list of features, at least momentarily. That is true by virtue of the definitions of the basic grammatical relations. However, entering such information into a lexicon is a separate step, not guaranteed by these definitions. A child may at first draw on only one relation to develop a lexicon (as with Adam), and he might not make an entry every time he encounters an example of an appropriate relation in adult speech. The fact that a single word never goes into different pivot classes for the same child reflects this restriction—at first, children assume that each word has one and only one classification.

Moreover, there is no assurance that a child understands adult speech correctly. Inappropriate classifications can occur. When they do, however, it is because words are used in the wrong grammatical relations, not because they are used in esoteric relations or in no relation at all. Such are the constraints within which child language exists. Utterances like *allgone shoe* can be understood in this light. Braine's subject either treated *allgone* as a modifier (and so as a word like *big* or

that) or *allgone shoe* as a complete but backward sentence (and so equivalent to the English *the shoe is allgone*)

Some children utter sentences both forward and backward for a time, the two directions expressing the same grammatical relation. It is as if some nouns were (for example) tagged [+ VP—] and others [+ —VP]. Thus we can hear both *ball hit* and *read mommy* as expressions of the subject and predicate relations. Braine (in press) lists several such examples. It is not necessarily the case, as sometimes has been thought (e.g., Slobin, 1966b), that children adhere to a fixed order of words when expressing the basic grammatical relations. It should be noted that contextual features, such as [+ —VP], show *logical* relations. They show *ordinal* relations in addition, only via a further principle that logical relations are expressed through the order of words. In languages other than English contextual features often control inflections and the order of words serves an altogether different function, for example, style.

A word classified with just one set of features can be used only in the corresponding relation. Eventually all words are classified in several ways, thus enlarging the distributional range of each word. However, additional features sometimes lead to temporary restrictions of range instead. Two of Brown's subjects, for example, used for a time only animate nouns as the subjects of sentences and only inanimate nouns as the objects of verbs (unpublished materials). Nouns apparently had been tagged in the lexicon as [+ NP, + —VP, + animate] and [+ NP, + V—, + inanimate], an enlargement of the feature roster produced a restriction in distributional range.

The question is sometimes raised whether or not children rely on semantic considerations in classifying words syntactically (e.g., Slobin, 1966a). Doing so would presuppose a link between semantic and syntactic information. Words alike on a certain semantic feature (say, activity) are all given the same syntactic feature (say, + V). Brown (1958) found evidence that children of three or four are alert to the semantic implications of nonsense words used as mass nouns, count nouns, or verbs. Braine (in press), using a technique like Brown's, concluded that whereas the classification of verbs might be assisted by semantic implications, the classification of nouns

probably is not. His observations are interesting and worth reporting in some detail.

Braine taught his 2-year-old daughter two new words, one the name of a kitchen appliance (*nuss*) and the other the name of the act of walking with the fingers (*seb*). Neither word was used by an adult in a grammatical context. However, the child used both words appropriately—*nuss* as a noun and *seb* as a verb, as in *more nuss* and *seb Teddy*. She also used *seb* as a noun, but never used *nuss* as a verb. There were sentences like *more seb* and *this seb*, but none like *nuss the vegetables*. Evidently there is no requirement that nouns be associated with things, although there is a requirement that verbs be associated with actions. Braine also observed his daughter using newly acquired Hebrew verbs as nouns, but he never observed her using nouns as verbs.

These observations show that although se-

mantic information is helpful in syntactically classifying words, such information is not identical with syntactic classification. *seb* was used as a noun, regardless of its association with action.

The child's productive use of both *seb* and *nuss* in sentences, even though the words had been introduced out of context, reflects the degree of freedom of child speech from the circumstances in which examples are encountered—a matter we return to later.

If children develop lexical features from the basic grammatical relations, how then are we to interpret the pivot and open classes? An answer is suggested by a chart prepared by Slobin (in press), which is reproduced here as Table 5. The chart shows examples of pivot words from the early grammars of children exposed to three different languages: English, German, and Russian. The examples have been collected from various diary stud-

Table 5 Pivot Structures in English, German, and Russian

Function of Pivot	Language		
	English	German	Russian
Modify, quality	<i>pretty</i> — <i>my</i> — <i>allgone</i> — <i>all</i> — <i>big</i> — <i>other</i> —	<i>armer</i> [poor]— <i>mein</i> [my]— <i>alle</i> [allgone]—	— <i>bo-bo</i> [hurt] — <i>khoroshaya</i> [good] — <i>tyu-tyu</i> [allgone]
Locate, name	<i>there</i> — <i>here</i> — <i>see</i> — <i>it</i> — <i>that</i> — — <i>on-there</i> — <i>up-there</i>	— <i>da</i> [there] <i>da-is</i> [there is]— <i>gukuk</i> [see]—	— <i>tam</i> [there]
Describe act	— <i>away</i> — <i>on</i> — <i>off</i> — <i>it</i> — <i>do</i> — <i>come</i> <i>I</i> —	— <i>bah</i> [away] — <i>an</i> [on] — <i>auf</i> [on] — <i>aus</i> [off]	— <i>tprua</i> [walk] — <i>bay-bay</i> [sleep] — <i>upala</i> [fell down] — <i>bukh</i> [fell down]
Demand, desire	<i>more</i> — <i>give</i> — <i>want</i> —	<i>mehr</i> [more]— <i>bitte</i> [please]—	<i>eshche</i> [more]— <i>day</i> [give]—
Negate	<i>no</i> — <i>don't</i> —	<i>nein</i> [no]— <i>nicht</i> [not]—	<i>net</i> [no]— <i>ne-nado</i> [don't]—

From Slobin, in press

as Slobin organized the chart to reflect certain semantic regularities—for example, that some pivots serve to modify meaning (*pretty, mein, bo-bo*), that others locate or name things (*there, da, tam*), that still others describe acts (*away, bah, bukh*). Such distinctions may indeed be important in child speech, it is impressive that a word for *allgone*, for example, is used as a pivot by each child. However, semantic factors do not explain the pivot-open distinction. Even if all children have use for a concept like “allgone,” the term representing it could appear as either a pivot or an open word.

In order to understand why the pivot-open distinction appears as it does we must note another regularity running through Table 5. Aside from negation (which is treated below), the pivots of Table 5 involve only certain sets of syntactic features—those marked by an asterisk in the preceding list. It is the case, apparently, that pivot words are never Ns or NPs, whereas open words are always Ns or NPs. Such a restriction would exist if pivot words could express only the basic grammatical relations of modification, predication, and main verb. From this point of view, the distinction between pivot and open classes is a superficial and imperfect reflection of the development of these three relations and its effects on a child's lexicon. The distinction necessarily appears in a distributional analysis because a child's lexicon is derived from the three basic grammatical relations of modification, predication, and main verb, and sentences constructed from this lexicon are limited to two or three words. Each of the observed relations yields N or NP as a contextual feature.

Why are the other basic grammatical relations—subject, object, and “head”—never a source of pivot words? One reason may be the following. Each such relation involves an N or NP in combination with some other category. By *not* establishing N and NP as pivot words a child treats N and NP as unmarked categories and all other categories as marked: every word is either an NP (or N) or a word that appears with an NP (or N). Such a division of the lexicon requires 4 distinct lexical entries—the 3 marked by an asterisk in the list above plus NP (or N). It is the simplest possible lexicon that can be derived from the 6 basic grammatical relations. If the marked-

unmarked distinction is reversed, with NPs (or Ns) as pivots, there are 5 distinct lexical entries, and if it is not established at all, there are 6. Children therefore seem to be guided by a principle of simplicity. Since Ns outnumber all other words in children's vocabulary at this point in development, simplifying nominal entries is the largest single simplification possible that does not lose contact with the basic grammatical relations.

All the distributional and featural characteristics of the pivot-open direction can be thus understood. Pivot words are either modifiers, predicates, or main verbs, open words appear with pivot words in the complementary relations. Open words appear without restriction because they are unmarked, pivot words appear with open words because they are marked. Modifiers, for example, cannot occur alone because they have the obligatory feature [+—N] and cannot occur with each other because they do not have the feature [+Det—]. Nouns appear alone because they have no contextual feature and appear with pivots because pivots have nouns as a contextual feature. Kelley (1967) has built one of these features—modification—into a computer program that successfully acquires certain aspects of English syntax.

Summary The basic grammatical relations penetrate deeply into the linguistic powers of children. We now summarize what has been said of them, exposing clearly the line of argument followed.

One basic grammatical relation—predication—appears to be present from the earliest moments of holophrastic speech. Later developments depend on an elaboration of this relation as well as an introduction of the remaining grammatical relations—subject, verb, object, and modification. All such developments produce forms that eventually become the deep structure of sentences.

We have reviewed two lines of change. One is the incorporation of subjects with predicates in children's speech, another is the construction of a lexicon where words are classified according to the grammatical relations they can occupy.

It is important to observe that the basic grammatical relations, combined with the definition of grammatical categories in terms of syntactic features, give children's grammar a certain necessary form. Without exception,

children construe everything understood in adult speech according to the basic grammatical relations, equally without exception therefore they identify words encountered in parental speech as possessing such features as [+N], [+Det—], [+—VP] Children may or may not *record* such information (a lexicon is not developed instantly), but merely to understand adult speech its vocabulary must at least momentarily be classified according to the features imposed by the basic grammatical relations Children's own speech is constructed according to the same basic principles—for children presumably understand most of what they say

Insofar as the basic grammatical relations reflect the innate abilities of children, the type of grammar just outlined will be developed regardless of the language to which a child is exposed It is a universal child grammar, and it leads to a convergence of child and adult grammar at the level of meaning no matter what language a child happens to be exposed to Other aspects of grammar also are universal and may be a reflection of children's innate abilities Syntactic features derived from the basic grammatical relations, such as [+—VP] and [+N], are what Chomsky (1965) called categorical features, they make such strings as *golf plays symmetrical* grammatically deviant However, categorical features do not exhaust the information contained in the deep structure of sentences In addition there are features, called subclassificational by Chomsky, which serve to eliminate such strings as *golf plays John* Features of the first type specify where a word can appear in a deep structure, for example, in NP but not in V Features of the second type specify how words coexist in deep structures, for example, *plays* takes only animate subjects and inanimate objects Subclassificational features cannot be developed from the basic grammatical relations

The differentiation of Adam's pivot class (Fig 5) produces a family of such subclassificational features The pivot class itself is based on the categorical features [+Det, +—N] It is conceivable that a universal hierarchy of features, much like the universal hierarchy of categories described by Chomsky (1961), is responsible for this differentiation If such is the case, the arguments developed earlier would again apply Sentences that vio-

late a subclassificational feature would be understood by adults through reference to a higher level in the hierarchy, and children's linguistic advancement would be the result of progressing from higher to lower levels in the same hierarchy

The Acquisition of Transformations

The deep structures of sentences are largely a reflection of children's innate linguistic abilities It is for this reason that such information can be totally abstract in sentences Deep structures become abstract when children learn the transformations of their language The interaction between linguistic experience and innate linguistic ability thus occurs here—in the acquisition of transformations—and here is the appropriate place to examine the role of parental speech Such is our guiding hypothesis

The present section reviews what is known of this interaction It can be viewed as a history of the way that children, beginning with a universal child grammar, diverge in the direction of the grammar of their local language We shall have occasion to trace the emergence of several transformations of English, and to examine the suitability of several psychological proposals—both traditional and otherwise—for the acquisition of language

The Emergence of Inflections We begin with the acquisition of certain morphological details Although inflections are usually not introduced through major formations, they are easily traced features of the surface structure of sentences, and they clearly illustrate some aspects of the way children learn to relate deep and surface structures

Table 6 lists the order of emergence of several noun and verb inflections in English (Bellugi, 1964) The data are based on observations of two children Also shown is the relative frequency of the same inflections in the speech of the children's mothers

There are several matters worth noting One is that the order of emergence is the same for the two children Order is the same even though the children's rate of development is radically different, one child taking twice as long to acquire the six inflections of Table 6 as the other A second point is that forms employing the same phonetic variants do not appear at the same time Three inflections have the same phonemic realization, -s

Table 6 The Emergence of English Inflections in the Speech of Two Children

Inflection	Age of Appearance (in months)		Combined Rank Order in Mothers Speech
	Adam	Eve	
Present progressive, <i>-ing</i>	28	19½	2
Plural on nouns, <i>-s</i>	33	24	1
Past on regular verbs, <i>-ed</i>	39	24½	4
Possessive on nouns, <i>-s</i>	39½	25½	5
Third person on verbs, <i>-s</i>	41	26	3

From Bellugi, 1964

These are plural marking of nouns, nouns marked for possession, and third person verbs. The last appears anywhere from 2 to 8 months later than the first, so it is not phonemic development that regulates the acquisition of inflections. Finally, the order in which inflections emerge in the speech of children is weakly correlated with the frequency of the forms in the speech of adults. The most glaring discrepancy involves third-person marking on verbs, which is third most frequent in maternal speech but last to emerge in child speech.

Now consider the equivalent phenomenon in the acquisition of Russian. Here matters are more complex. The language is highly inflected, and for this very reason more interesting. Slobin (in press), after examining a number of reports in the Russian literature, reconstructed the following chronology. The first inflections to appear are the plural and diminutive marking of nouns and the imperative marking of verbs. This happens at 22 months or so. Next to appear are various case, tense, and person markings on verbs—a complex story to which we return shortly. Then appears the conditional marking of verbs, much later than the inflections of case, tense, and person, even though the conditional is structurally simple in Russian. After this, nouns come to be marked for various abstract categories of quality and action, and finally, last by a large margin, appears gender marking of nouns and adjectives.

Slobin argues that three major factors influence the point at which inflections appear in linguistic development. One is the frequency

of occurrence of an inflection in adult speech, we see the effects of this factor in Table 6. A second is the superficial complexity of an inflection (e.g., the accusative emerges late in German, where it is relatively complex, and early in Hungarian, where it is simple). The third is something Slobin calls the "semantic content" of an inflection, which probably refers both to the deep structure of sentences and to the sheer intellectual difficulty of the idea represented by an inflection. The relatively late appearance of the Russian conditional, for example, is explained by its difficult semantic content.

Gender in Russian is an ambiguous case. It is by far the most difficult aspect of Russian morphology for children to master: errors typically continue until 7 or 8 years. Slobin attributes the confusion over gender to its difficult semantic content: most nouns are arbitrarily marked, some nouns with real implications of gender are marked in the wrong way, etc. However, the problem may not be the semantic difficulty of gender at all. Gender in adult Russian appears to have little or no semantic content. But for children it may have definite semantic implications. If this is correct, then the difficulty children experience with gender-marking is not a matter of deep complexity but of superficial complexity. If a Russian child reacts to gender-marking at an early age, he will *exclude* these inflections from "inappropriate" words. Thus gender-marking will be slow to develop, for a child must learn a large number of localized and superficial rules.

It is interesting to note in passing that public education in a society seems to be withheld until children have mastered morphology. The morphology of English, which poses relatively few problems, is largely mastered by age 4 or 5. Schooling begins at 5 or 6. The morphology of Russian, which poses many more problems, is not mastered until 7 or 8. Schooling begins at 7. The intellectual readiness of children for school apparently has traditionally been judged by mastery of one of the most peripheral parts of language.

In keeping with the visibility of morphology, it is not surprising that when inflections are overgeneralized, the phenomenon attracts a good deal of attention. All parents know that children regularize strong verbs

(*runned, goed, sitted*, etc.) and nouns (*foots, mouses, tooths*, etc.) However, the actual development of such forms is more complex than is usually realized. Tracing their history is instructive on a number of points.

Overgeneralization, Simplification, and the Question of Overt Practice. English has a number of strong verbs, verbs with irregular past tenses. There are also nouns with irregular plurals. Although children long regularize these forms—adding *-ed* to the verbs and *-s* to the nouns—this is not the way they begin (Ervin, 1964). Initially, strong verbs appear in child speech in the correct irregular form—*came* instead of *comed*, *ran* instead of *runned*, and *did* instead of *doed*. The development of irregular plurals shows the same phenomenon—*feet*, *mice*, and *teeth* appear in child speech before *foots*, *mouses*, and *tooths*. Regularization, when it occurs, is a step forward.

The explanation of the early appearance of such correct irregular verbs and nouns has to do with the frequency of these forms in adult speech. Strong verbs are by far the most frequent verbs, and strong nouns occur commonly also. Children are thus given many opportunities to discover the association of the underlying morphemes (past) and (plural) to these words, and they make such discoveries early.

But for many irregular verbs and nouns each word is a case unto itself, no rule covers more than one. For others, only 2 or 3 words are subject to the same rule (*lead-led, read-read*).³ Because of the limited scope of the strong forms, the weak, or regular, forms remain untouched when the strong forms change. A child who only knows how to say *feet*, *mice*, or *oxen* may have in mind plurality when he says *two box*, but he cannot express this underlying idea. Should it be *beev*, *bikes*, or, possibly, *boren*? Obviously, it is *box*.

It is general rules that children seek, indeed, they seek the simplest such rules possible. The evidence is dramatic. Ervin (1964) searched her records of child speech for the first examples of the regular past-tense and plural inflections. Correct usage of irregular forms was already present. For verbs she first found the regular *-ed* on these same irregular

forms! Overgeneralizations apparently occurred before anything existed in speech to generalize from. Plural inflections on nouns first appeared with weak forms, but very shortly thereafter with the strong forms as well.

The finding with verbs, of course, is an illusion. Strong verbs are frequent in child speech, just as in adult speech. Accordingly, Ervin had a better chance of observing *-ed* on strong than on weak forms. However, the superior frequency of strong verbs does not influence the force of Ervin's observation. Children treat strong and weak verbs alike, and for this reason they encompass strong verbs within the regular past-tense rule as soon as it is formulated. The same is true of plural inflection on nouns. The gap between the first appearance of *-s* and its overgeneralization to irregular forms is brief, usually only a matter of weeks.

Slobin (in press) refers to such encroachments of regularity as "inflectional imperialism." There are no political connotations in the fact that inflectional imperialism is a major factor in the acquisition of Russian; it rather has to do with language. To quote Slobin:

Overregularizations are rampant in the child's learning of Russian morphology—small wonder, what with the great variety of forms within each category, determined on the bases of both phonological and grammatical relations. For example, not only must the child learn an instrumental case ending for masculine, feminine, and neuter nouns and adjectives in singular and plural, but within each of these sub-categories there are several different phonologically conditioned suffixes (not to mention zero-endings, morphologically conditioned suffixes, and other complications). The child's solution is to seize upon one suffix at first and use it for every instance of that particular grammatical category.

In the evolution of the instrumental inflection, Gvozdev's son Zhenya first employed *-om*, the suffix for masculine and neuter nouns in the singular. Zhenya used *-om* on all nouns, including the feminine nouns that were at that time most abundant in his speech. The corresponding feminine form, *-oy*, appeared only some time later, but when it did, *-oy* immediately dominated the original inflection,

³ I am indebted to Dan I. Slobin for reminding me of these cases.

-om Much later, *-om* reappeared in Zhenya's speech, this time to be used appropriately. An experiment by Zakharova (1958) found the same sequence of events in a sample of 200 children. Such is inflectional imperialism.

Inflectional imperialism in Russian and English do not seem at first glance to be the same. The English regular verbs often invade a domain where no rule exists at all, the Russian suffix *-oy* invades where a rule is already in force. One appears to fill a vacuum, whereas the other seems truly imperialistic. The difference, however, is more apparent than real, for on closer examination we can see that the two cases demonstrate the same phenomenon.

The phenomenon is that children always strive to formulate the most general rule possible. That is what English-speaking children do in extending regular inflections to irregular forms. Instead of having several ways of expressing (past) or (plural), they have only one for each. Russian children do the same. Both *-om* and *-oy* have multiple uses in adult Russian, but *-om* has fewer (two) than *-oy* (five). Russian children thus first select the suffix with the fewest uses, as Slobin points out.

One reason for making such a choice is that a rule formulated for the morpheme *-om* can be more easily discovered. The morpheme *-om* has fewer exceptional uses than has the morpheme *-oy*. Later, when a child also discovers that gender is a grammatical category, the balance between the two inflections changes. To mark gender as well as to mark the instrumental case, *-oy* is the inflection with greater generality, for it applies to some masculine nouns as well as to the large number of feminine nouns then in a child's vocabulary. The imperialism of *-oy* thus results from Russian children doing with *-oy* what American children do with *-ed*, which is to follow the rule of larger scope.

Russian- and English-speaking children are alike in yet another respect. Inflectional imperialism in the acquisition of morphology clearly shows that overt practice has little influence on linguistic development. When we observe one form imperialistically driving out another, we observe a form that has received little or no overt practice displacing another that has received a great deal of overt practice.

The inflection of regular verbs in the past-tense in English was so rare in the speech of Ervin's children that *-ed* first appeared on the strong verbs. These verbs, in contrast, had been used with their correct irregular inflections for months and in large numbers. Such extensive practice offered no protection against the tendency to express the past tense in a single rule. Since correct irregular forms are *replaced* by incorrect regularizations, it is clear that children actually expressed past time in the original correct forms. The same situation exists in the development of Russian morphology. The masculine suffix *-om* is well practiced but easily and immediately displaced by the feminine suffix *-oy*.

We therefore can draw at least a negative conclusion concerning the role of parental speech in language acquisition. Its role is not to provide children with opportunities to practice. As we shall see later, the acquisition of morphology is not different in this respect from the acquisition of other transformations.

Imitation. One traditional view of language acquisition holds that the process is advanced through imitation. However, there are several reasons to doubt that imitation plays a role in language acquisition, and it is appropriate to consider the question at this point.

But first we must clear up an ambiguity. The word "imitation" is used in two quite different senses, only one of them can be applied to language acquisition. In one sense, "imitation" refers to a process whereby one organism comes to resemble more and more closely another. The trait on which the resemblance develops must necessarily be within broad limits arbitrarily variable—resemblance in height, for example, is not the result of imitation. However, all sorts of other things develop through imitation in this sense, etiquette, driving a car on the left side of the road in England, typing, writing prose in the style of Faulkner—all are included. In this sense, it is also true that children acquire language through imitation.

There is a second, more technical use of the word "imitation"—details of behavior—for example, plural inflections on English nouns—are first acquired by copying the behavior of a model. Such a view of language acquisition was presented by Allport (1924), and it has appeared in psychology texts ever since,

but it is the technical sense of "imitation" that is inappropriate for language acquisition

There is no question that children imitate the speech of adults a good deal. In the records collected by Brown, fully 10% of children's speech at 28 to 35 months is imitative, as, for example, in such exchanges as the following

Adult	Child
Oh, that's a big one	big one
But he was much bigger	
than Perio	big a Perio
Salad dressing	salad dressing
That's not a screw	dat not a screw
Are they all there?	all dere?

However, the fact that children imitate the speech of adults does not mean that the process of acquisition is imitation. It is clear from examples given in previous sections that not everything in child grammar originates in such a fashion. *It runned, allgone shoe, a that man*, for instance, have no models in adult speech, but they are grammatical within a child's system.

Nonetheless, it is possible that forms are first introduced into a child's speech through imitation. As long as grammar is not fully developed, a child might produce such utterances as *a that man*, and yet still enrich his grammar through the imitation of well-formed examples. In this case, imitations will be "advanced" grammatically relative to spontaneous speech.

Ervin (1964) looked into this possibility by comparing children's naturally occurring imitations to their free speech. She found that the grammatical organization of the imitations was identical to the organization of the free speech. Only one child in Ervin's sample of five was an exception, and her imitations were more primitive than her spontaneous speech. For all these children therefore imitations were not "grammatically progressive," as Ervin put it.

The result reflects a general characteristic of child speech. There is a strong tendency among children to include nothing in the surface structures of sentences that cannot be related to deep structures—nothing for which the transformational derivation is not known. The principle encompasses imitation as well as spontaneous speech. If a child does not yet include the progressive inflection *-ing* in his

speech, he also will not imitate *-ing* in the speech of adults, particularly if the adult model is long relative to his memory span (see Slobin, 1964, McNeill, 1966a). *Adam's nose is dripping* might be imitated *Adam nose drip* but probably not *Adam nose dripping*. It is for this reason that imitation can be used as a test of children's productive capacities, and it is for this reason also that children's early utterances are patterned as deep structures. Slobin and Welsh's (1967) stunning observation of a child imitating a sentence containing a relative clause with two conjoined sentences reflects the same principle. In all cases, children exclude superficial forms when they cannot be related to deep forms.

The resistance of children to new forms sometimes goes to extravagant lengths. Consider, for example, the following exchange between one mother and her child (from McNeill, 1966a)

Child	Nobody don't like me
Mother	No, say "nobody likes me"
Child	Nobody don't like me

(eight repetitions of this dialogue)

Mother	No, now listen carefully, say "nobody likes me"
Child	Oh! Nobody don't likes me

Although children do not ordinarily behave differently when imitating and speaking, it is possible to instruct children to imitate, as Slobin and Welsh (1967) and Fraser, Brown, and Bellugi (1963) have done. Under these circumstances, a child's imitations may depart from his grammar. But instructed imitation is not typical of the ordinary circumstances of child speech, and phenomena observed here cannot be extended to the actual acquisition of grammatical structure.

Rather than serve didactic purposes, imitation often seems to be carried out in play. It therefore is the opposite of instruction, if indeed it has any effect at all, rather than change his grammatical system a child manipulates it, often in fantastic ways. Take as an example one of Brown's subjects, who, start-

ing from an ordinary imitation, elaborated on it in an almost fuguelike manner (mentioned by Slobin, 1964, also McNeill, 1966a)

Adult That's the tattooed man
 Child Tooman Tattoo man Find too tat-
 too man Tattoo man Who dat?
 Tattoo Too man go, mommy? Too
 man Tattoo man go? Who dat?
 Read dat Tractor dere Tattoo
 man

Wen (1962) found many examples of similar grammatical play in the presleep soliloquies of her 2½-year-old son. The child selected a particular paradigm—sometimes grammatical, sometimes phonological—and then elaborated a stream of examples. The following uses a syntactic paradigm, it might be considered the linguistic equivalent of repeatedly building up and knocking down a tower of blocks

go for glasses
 go for them
 go to the top
 go throw
 go for blouse
 pants
 go for shoes

We thus arrive at the same negative conclusion as before: the role of parental speech in language acquisition is not to supply opportunities for children to practice. The practice of forms already in a child's grammar (e.g., *dug*) contributes nothing to the viability of the forms when they come into conflict with a child's changing system, such is the case in inflectional imperialism. The practice of forms not yet in a child's grammar simply does not occur, such is the case with imitation. The dominating factor is a child's own system of rules. The contributions of parental speech are always most severely filtered through this system.

What, then, of adult speech? To see even the beginning of an answer to this question, we must examine more closely the acquisition of transformations. It is here, as noted before, that the interaction of a child's linguistic abilities with his linguistic experience takes place.

Negation in the acquisition of English. The study of how children acquire transformational systems has barely begun. One would like to have detailed observations of a wide

range of transformational relations, as it is only through investigations of such scope that our views on the process of acquisition can be evaluated. However, few transformations have been investigated from a developmental point of view, and even here the investigations are incomplete.

Menyuk (1964a, 1964b, 1964c, 1968, in press) has pursued a number of surveys of linguistic development. They possess the desired degree of scope—a large variety of sentence types being examined—but the results are presented in terms of a kind of contrastive analysis, and little can be discovered from it about the actual acquisition of transformations.

More direct analyses of transformations are presented by Klima and Bellugi (1966), Brown, Cazden, and Bellugi (1968), and Bellugi (1967). These studies are so far confined to the acquisition of two transformational systems—negation and questions—by the three Biblically named children in Brown's study, Adam, Eve, and Sarah. We shall first consider the emergence of negation and then of questions.

Brown and his colleagues have organized their longitudinal records into a series of "stages." The stages are not intended to have linguistic or psychological significance, although some of them in fact coincide with true junctures in development. Instead, stages are defined in terms of average utterance length, measured in morphemes, and merely provide a way of comparing children whose rates of development are different. Figure 6, taken from Brown et al. (1968), shows the relation between chronological age and mean utterance length for the three children of Brown's study. Roman numerals indicate the stages into which the analysis has been divided; the following discussion focuses on the first three of these.

At the first stage, coinciding with the appearance of pivot constructions, children utter such negative sentences as the following (Klima and Bellugi, 1966)

No wipe finger
 More no
 No a boy bed
 Not fit
 No singing song
 No the sun shinning

Fig 6 Mean utterance length as a function of age in three children (Brown et al, 1969)

No play that
Wear mitten no
Not a teddy bear
No fall!

The form of these sentences is fixed, simple, and universal. They all consist of a negative operator (*no* or *not*) plus an otherwise affirmative sentence. The internal structure of the sentence, if any, remains undisturbed by the negation—the *sun shining*, *play that*, and *a teddy bear*, for example, are all possible affirmative sentences. The earliest schema for negation, then, is Neg + S. Since a negative operator (*no*) sometimes appears after sentences instead of before them, there also is the alternative form, S + *no*.

According to Slobin (1966), Gvozdev's son Zhenya also produced negative sentences in accordance with these schemas. Whereas an adult would say *nyet nikavo* (literally, "not no-one"), Zhenya said *nyet kavo*, reducing the well-formed double negative to the single negative required by the schema Neg + S. French children use *non* or *pas* in an analo-

gous fashion (Grégoire, 1937), and Japanese children do essentially the same thing with *nai* (McNeill and McNeill, 1968).

Some 2 to 4 months later, depending on the child, Klima and Bellugi found a flowering of negative forms. Compared to the two simple forms of negation of the first period, there are now seven distinct types:

I can't catch you
We can't talk
I don't sit on Gomer coffee
I don't like him
No pinch me
No Rusty hat
Touch the snow no
This a radiator no
Don't bite me yet
Don't leave me
That not "O," that blue
There no squirrels
He no bite you
I no want envelope

Certain of these sentences are well-formed in English—I *can't catch you*. Others are

identical to the negative sentences of the first stage—*no pinch me*. The rest are intermediate, more complex than the primitive negatives of the first stage but not yet well-formed—*he no bite you*.

Although some of the sentences of the second period are apparently well-formed, the grammar yielding them is not yet the grammar of adult English. In fact, *I can't catch you* and *he no bite you* have the same basic structure for children at this point in development.

In adult English, sentences such as *I can't catch you* possess a deep structure of roughly the form Neg + NP + Aux + VP (Klima, 1964). A transformation relates the deep structure to the surface structure of *I can't catch you* by removing Neg from its location at the beginning of the sentence to a position behind the modal verb *can*. The process is called "Neg-transportation." In other sentences—*I don't like you*, for example—there is no modal verb in the underlying structure, but a second transformation introduces the modal *do* into the surface structure as support for negation. Thus the meaning of *I don't like you* is really the meaning of *I n't like you*, since *do* serves merely to support the negation of the sentence. This process is called "do-support."

The only well-formed sentences listed among the child examples given above were sentences of these two types. If children indeed utter well-formed sentences in such cases, transformations for Neg-transportation and do-support must be involved. However, there is no indication in the second stage of development that do-support exists, although a precursor of Neg-transportation might already be established.

The auxiliaries *can* and *do* appear only in the context of Neg at this stage. There are no affirmative sentences such as *I can do it*, *can I have it?*, or *do you think so?* Children instead say *I do it*, *I have it?*, and *you think so?*, all without the modal verbs *do* and *can*. Klima and Bellugi represent the fact that *do* and *can* are restricted to negation by including in the children's grammar a constituent they call the negative auxiliary (Aux^{neg}). Aux^{neg} in turn eventually leads to *don't* and *can't* as two lexical items. Aux^{neg} can be regarded as an undifferentiated amalgam of negation and "auxiliary verbness." Its two components will

not be distinguished until some months later.

Klima and Bellugi set down the following rules for the second stage

$$Aux^{neg} \rightarrow \left\{ \begin{array}{l} Neg \\ V^{neg} \end{array} \right\}$$

$$V^{neg} \rightarrow \left\{ \begin{array}{l} can't \\ don't \end{array} \right\}$$

$$Neg \rightarrow \left\{ \begin{array}{l} no \\ not \end{array} \right\}$$

The constituent Neg appears in *that no fish school*, *he no bite you*, and other sentences of this type.

Since Aux^{neg} appears immediately after the subject NP of a sentence and immediately before the main verb, negation is already positioned appropriately, so Neg-transportation is not necessary to produce surface structures of the type observed. Moreover, since there is no evidence for modal verbs existing independently of negation, a transformation for do-support is likewise not necessary to obtain the surface structures of the second stage. By Klima and Bellugi's analysis, then, such sentences as *I don't like you* and *he no bite you* are fundamentally alike. Neither includes a modal verb, both include the constituent Aux^{neg} , and the transformations for Neg-transportation and do-support are not involved. Clearly therefore the well-formedness of *I don't like you* and *I can't catch you* is illusory.

There is another interpretation of sentences like *he no bite you*. Such sentences include internal negation and in this respect differ from the more primitive sentences observed in the first stage of development such as *no the sun shining*. One innovation occurring between the first and second stages of development may therefore be the appearance of Neg-transportation. If we accept this interpretation the consequence for Klima and Bellugi's grammar is merely to reverse the order of elements assumed to underlie negative sentences. Instead of NP + Aux^{neg} + VP, as in Klima and Bellugi, it becomes Aux^{neg} + NP + VP, with the constituent Aux^{neg} being developed as before.

Neg-transportation now applies to every sentence, including *I can't catch you*. One advantage of this interpretation is that it leaves room for the negatives—such as *no pinch me* and *no Rusty hat*—that appeared in the

second stage but seem to be relics of the first. In Klima and Bellugi's analysis, they are truly relics, coming from an earlier and unintegrated system. In the alternative analysis they are identical to the underlying form of all negative sentences in the second stage, except

The transformation for *Neg*-transportation at the second stage is

$$Aux^{neg} + NP \rightarrow NP + Aux^{neg}$$

This transformation must apply to the first two phrase markers above, as they meet the condition of the transformation, *I can't catch you* and *he no bite you* result. However, the transformation cannot apply to the third phrase marker, since it has no NP after Aux^{neg} , the sentence remains *no pinch me*. According to the alternative interpretation, therefore, such sentences as *no pinch me* are untransformed deep structures.

Notice that the well-formedness of *I don't like you* and *I can't catch you* is illusory in the alternative analysis as well as in Klima and Bellugi's analysis. The basic kinship of these sentences to *he no bite you* remains undisturbed by assuming the existence of a transformation.

Two to six months later, again depending on the child, sentences of the following types occur

Paul can't have one
This can't stick
I didn't did it
You don't want some supper
Donna won't let go
No, it isn't
I am not a doctor
This not ice cream
They not hot
I not crying
He not taking the walls down
Don't kick my box
Don't touch the fish
Ask me if I not make mistake
I not hurt him

that they have no subjects—still a common omission of children's sentences at this time.

Consider, as examples, the three phrase markers below. The first is the deep structure of *I can't catch you*, the second of *he no bite you*, and the third of *no pinch me*.

There are a few new developments in the third stage, though apparently not so many as in the second, however, as is often the case in child language, superficial changes are not a valid guide to changes taking place in a child's underlying system. Grammar can develop "silently." Whereas the five new forms of the second stage resulted from changes (in Klima and Bellugi's analysis) of little scope, the negative sentences of the third stage come from a grammatical system that has been fundamentally altered: there are now auxiliary verbs, a transformation for *do*-support is now present, and, in Klima and Bellugi's analysis as well as in the alternative analysis previously given, there is a transformation for *Neg*-transportation.

A basic development is the first appearance of the English system of auxiliary verbs. Unlike the second stage, there are now affirmative sentences with modal verbs, as in *I can do it* and *can I have it?* Negation is therefore no longer tied to the auxiliary, as in the second stage, for the constituent Aux^{neg} has been differentiated into its negative and auxiliary components. Since *do* and *Neg* co-exist in the surface structure but are not united in the deep structure, a transformation for *do*-support becomes necessary to derive such sentences as *I don't like you*. The continuity of surface forms between the second and third stages masks a basic discontinuity in the grammar. One indication of the discontinuity is that sentences based on the schema $Neg + S$ no longer appear; the schema has been made abstract by the changes of the third stage.

The development of the auxiliary system is very rapid and pervasive during the third

stage It is as if the auxiliary, once freed from negation, flowed in to fill all the available space in a child's grammar As Bellugi (1967), who has studied these developments closely, puts it

The change suggests a carefully prepared complex system which is beginning to be set in and intricately hooked up to the children's previous language systems If the change were not so widespread, and occurred over a long period of time in many little separate aspects, nothing would be surprising in this development It is the fact that much of the apparatus comes in in a relatively short period of time and appears in a variety of structures that surprises us (p 90)

Table 7 gives some impression of the pace of these changes In it are shown the number of times that one child, Eve, used modal verbs in several different grammatical contexts in three successive samples of her speech, the samples were collected over a period of 1½ months Along with a growth in numbers is a growth in variety—more and more modal verbs appear with more and more main verbs, tenses of verbs, subjects, etc

Negation in English is a complex system Klima's (1964) analysis, for example, includes almost two dozen phrase-structural and an equal number of transformational rules The sketch presented here—including as it does only three phrase-structural and two transformational rules—is clearly highly selective and incomplete Bellugi (1967) goes somewhat farther, but detailed understanding of the entire system is far from being at hand, as already noted, the work has only begun

Two other aspects of children's negation should be mentioned, however Both illustrate the autonomous and inventive character of child grammar and its indirect dependence on the speech of adults

Table 7 The Use of Modal Verbs by One Child

Context	Age (months)		
	26 5	27	27 5
Affirmative	8	20	27
Negative	6	12	14
Yes-No question	—	4	12

From Bellugi, 1967.

One has to do the rather special corner of the English negative system that controls such verbs as *think*, *believe*, *anticipate*, *expect*, and *want* All have the unique property that when in sentences with embedded object complements, either these verbs or the verb of the complement may be negated, and meaning does not change (Lakoff, 1966) Compare, for example, the following quartet of sentences, the first pair of which includes a verb open to this option, and the second pair of which does not

- 1 I think that he won't come on time
- 2 I don't think that he will come on time
- 3 I know that he won't come on time
- 4 I don't know that he will come on time

Sentences (1) and (2) mean the same thing, whereas (3) and (4) do not

For the small set of verbs admitting such moveable negation, Bellugi counted the number of times each option was employed in the speech of the parents of Adam and Sarah (Eve's records contained no example of such embeddings) The verbs most often used were *think* and *want*, and in all utterances except one, negation fell on the matrix sentence *I don't think that he will come in time* was more frequent by a large margin than was *I think that he won't come on time* Such is the linguistic evidence given to Adam and Sarah

However, in the children's own speech, precisely the opposite arrangement dominated This was the case even though negation appeared elsewhere in matrix sentences at this stage—as in *I don't know that* The following is an exhaustive list

He thinks he doesn't have nothing
 I think it's not full'd up to the top
 He thinks he doesn't have to finish it
 I think we don't have a top
 I think he don't like us no more
 I think I can't find white
 I think I don't better cut it
 I think I don't know what it is
 I think I don't

The explanation of the difference between what children do and what is presented to them is simple Verbs such as *think* and *want* are exceptions to the general rules of negation

in English Unexceptionable verbs are not open to the option of moveable negation in this way Children, if they have worked out the general rules of negation but not yet the exceptions, will treat *think* as any other verb (so that negation of the matrix verb is reserved for the improbable situation where a child is *not* engaged in thought *and* he is talking about it) They will do so even though they are contradicted by the evidence of parental speech We have again an indication of the inviolability of children's grammar and the strong filtering effect it exerts on the speech of adults

Another phenomenon in the acquisition of negation similarly reveals the autonomy of grammar, in this case that children's grammar is autonomous when it changes just as when it does not In English, adults say affirmatively, *I want some supper*, and at an early point in development children do the same (Bellugi, 1964) To negate such utterances, adults may either say *I want no supper* or *I don't want any supper* Children at first use neither of these forms, but say *I don't want some supper* After a few months, however, the grammar changes, and denial takes the form of double negation, as in *I don't want no supper* It is only after many months that children say *I don't want any supper* Thus the order of appearance of pronouns in negative sentences is *some-no-any* Other pronouns built on these forms—for example, *something, no one, anybody*—behave in the same way

Sentences with *some*, such as *I don't want some supper*, occur at the second stage of negation described above, and result from the insertion of *don't* as an Aux^{neg} into such affirmative sentences as *I want some supper* A child receives no examples of this process in the speech of adults, it is an autonomous consequence of his own grammar The double negatives of the next stage are even more interesting The middle-class parents of children who say *I don't want no supper* do not themselves use double negatives, indeed, Cazden (1965) found some indication that children exposed to a double-negative dialect differ both from middle-class children and from the dialect to which they are exposed Middle-class parents, far from providing examples of double negatives, would tend to correct such utterances with one or another of the well-formed forms of denial

Bellugi (1967) interprets the double negatives of the third stage as "negative coloring"—a kind of emphatic denial—although it is unclear of what negative coloring consists, except a tendency to use double (and sometimes triple) negatives It is also unclear why there is not "affirmative coloring" in cases of emphatic assertion, if indeed emphasis has anything to do with double negation Although negative coloring might play a role in the double negatives of the third stage, it seems also that they are a natural development of the form of negation in the second stage, for some speculations along this line, see McNeill (in press)

The exclusive schema for negation in the first stage is Neg + S or S + *no* In the second stage, sentences adhering to these schemas continue to appear but they are no longer the exclusive means of negation In the third stage, negation based on these simple schemas disappears completely As was pointed out earlier, these schemas also appear in the acquisition of French, Russian, and Japanese, at least It is possible therefore that they are the universal starting points for negation

Let us propose that a fundamental ability for negation, from which all children build, allows children to deny a proposition by affixing to it something like a minus sign If this is actually the case, all children would commence their linguistic careers with one or another of the two schemas mentioned before, and all languages would have sentence-external negation as the deep structure of negative sentences The suggestion is identical to a remark made by Grégoire in 1937 (p 169, quoted by Braine, in press) "*pas* devance [la phrase] à la façon d'un sign algebrique qui l'annule"

From such a beginning, children develop in two general directions On the one hand, the semantics of negation evolves from its primitive starting point, whatever that may be, to a level where distinctions are drawn between such different forms of negation as, for example, *no* (*I don't want it*), *no* (*it is untrue*), and *no* (*it is not here*) On the other hand, children must discover the syntax of negation of their local language—a process traced in part for English in the preceding pages

Let us briefly consider semantics Bellugi (1967) reports an impression that the mean-

ing of negation develops quickly. In the first stage of development, negation seemed, diffusely to mean refusal, rejection, or displeasure. By the second stage, however, a number of examples appeared where a child clearly negated the content of a previous proposition.

Adult: Daddy's getting old, huh?
 Child: No, I get old.
 Adult: That's your valentine.
 Child: No, Becky valentine.

McNeill and McNeill (1968) found a similar sequence in a study of the development of negation in Japanese children. An initial incoherent period, where denial seemed to depend on the absence of an object, was followed within a few months by the emergence of a single semantic contrast between the denial of the truth of propositions and the denial of the existence of objects or events—that is, by the form of negation also observed by Bellugi. McNeill and McNeill (1968) found that negation in the sense of rejection or refusal did not appear until some months later.

When a child says, for example, *no, Becky valentine*, he denies the truth of an intrinsic predicate—that the valentine is Becky's. If, as previously claimed, intrinsic predicates are the first form of predication to appear in child

language, the initial meaning of the “algebraic minus sign” must be the negation of such predicates. Only later, when extrinsic predication also becomes available, will children negate the existence of things or events. The first distinction drawn in the semantics of negation therefore will be between the denial of truth and the denial of existence.

McNeill and McNeill (1968) analyzed the semantic system of Japanese negation into three such contrasts, and then traced the emergence of each. It is conceivable that the same system applies to English negation also, and that children learning English acquire the system in a similar way.

Figure 7 shows the Japanese arrangement. The contrast between “Truth” and “Existence” refers to the negation of intrinsic and extrinsic predicates, respectively. The contrast between “Entailment” and “Nonentailment” refers to the difference between, for example, *no, that's an apple, not a pear* and *no, that's not a pear*. Both deny the truth of an intrinsic predicate (as in *that's a pear*), but in *no, that's an apple, not a pear*, the denial of one predicate “entails” the contrasting truth of another (*that's an apple*). The examples above from Bellugi (1967) apparently are of the entailment type. A final contrast, between “Internal” and “External,” refers to the difference between denial on internal grounds (e.g., *I*

Fig. 7. The organization of negation in Japanese. Negative terms in Japanese and English are located at the appropriate corners. The English examples are merely representative of each contrast. *No, it is a pear (and not an apple)*, versus *no, it isn't a pear*, versus *no, it didn't happen that a pear was thrown through the window*, versus *no, I don't want a pear* (McNeill and McNeill, 1928).

don't want it to happen) and denial on external grounds (e.g., *it didn't happen*)

As already mentioned, the Japanese children studied by McNeill and McNeill (1968) developed first the contrast between Truth and Existence. A few months later, they began to honor also the contrast between Internal and External. Before this time their expression of refusal took weirdly dogmatic form: the Japanese expression for "I don't want" (*uya*) was not used in situations where refusal was evidently intended (as in reply to "Let's do x"), but instead there appeared the expression for "it doesn't exist" (*nai*, an adjective). Thus, exchanges like the following occurred: "Let's give your sister some of your ice cream"—"It doesn't exist." The children expressed a lack of willingness with a term already known to express a lack of existence, clearly, the distinction between Internal and External did not yet matter. Finally, after several more months, the contrast between Entailment and Nonentailment appeared.

The entire structure represented in Fig. 7 emerged within a period of 4 to 6 months. Although it may be true that semantic development is generally slower than is syntactic development, that is not the case with negation. Accepting Bellugi's examples at face value, entailment-nonentailment appears in the language of American children when negation is still fused syntactically with the auxiliary system, and a number of months before the transformations of neg-transportation and do-support make their first appearance.

The Development of Questions Questions at the outset are simple in the extreme, and in this respect are like negation. Rising intonation, or the use of one of a few Wh-words, is the only interrogative device. Nonetheless, even very young children distinguish between yes-no and Wh-questions—asking, for example, both *see hole?* and *what doing?*

The following account will concentrate on the development of Wh-questions and, within this limit, will concentrate on the second and third stages of development defined by Brown et al. (1968). The first stage comprises essentially the simple system just described.

In the second stage children ask Wh-questions of the following kinds:

Where my mitten?
What me think?
What the dollie have?
Why you smiling?
Why not he eat?
Why not me can't dance?

A clue as to the structure of such questions lies in the fact that in every case except one deleting the Wh-word (or *why not* in the case of negative questions) leaves a "grammatical" sentence as a residue. *My mitten*, *me think*, *you smiling*, *he eat*, and *me can't dance* are all possible declarative sentences in the second stage; the only exception is *the dollie have*, which lacks an NP-object. In general therefore, Wh-questions are formed simply by using a Wh-word to begin a declarative sentence, the sentence otherwise being left undisturbed.

Questions asking *why* and *why not* are not different from other Wh-questions, although the distribution of the former pair is more restricted. *Why not* itself seems to be a single Wh-word possessing negative import, not a construction made up of *why* and negation as separate parts. More significantly, both *why* and *why not* tend to be restricted to discourse exchanges in which the declarative part of the question comes from a previous utterance of an adult and the Wh part comes from the child. Table 8 presents some examples from the speech of Adam and his mother (Brown et al., 1968). The other Wh-words available to children in the second stage of development do not depend on such discourse exchanges. McNeill (1963) found a discourse restriction similar to the restriction of *why* and *why not* in children's use of personal pronouns—in its first occurrences the first-person pronoun, *I*, always followed adult sentences with *you*.

It is clear from Table 8 that Adam's rule for deciding between *why not* and *why* is to choose the former when his mother's sentence is negative and the latter when it is affirmative. However, it is difficult to say what semantic constraints exist for Adam's *why* and *why not* questions. He wants to know, for example, *why you see seal?*, *why me bend that game?*, and *why not me careful?* Such questions suggest that although Adam probably seeks an explanation when he asks *why* or *why not*, his conception of

Table 8 The Restriction of *Why* and *Why Not* Questions by Discourse

Mother	Adam
He was playing a little tune	Why he play little tune?
I see a seal	Why you see seal?
You bent that game	Why me bent that game?
Well, because she wanted to	Why she want to?
I think it's resting now	Why it's resting now?
I guess I'm not looking in the right place	Why not you looking right place?
Because you weren't careful	Why me not careful?
I don't see any	Why not me can't dance?
You're going to have to buy another one and give it to Ursula because you're breaking that one	Why not me break that one?

From Brown, Cazden, and Bellugi, 1968

an explanation is remote from an adult's. It would be surprising, of course, if it were otherwise. Piaget (1924) long ago demonstrated that children are unable to conceive of true explanations at Adam's age. Nonetheless, the possibility of explaining things—as opposed to knowing what counts as an explanation—apparently exists early in development.

Wh-questions in the third stage reveal a number of interesting features. Some examples from Klima and Bellugi (1966) are the following:

Where small trailer he should pull?
Where the other Joe will drive?
What he can ride in?
What did you doed?
Why he don't know how to pretend?
Why the kitty can't stand up?
How he can be a doctor?
How they can't talk?

The third stage, it will be recalled, is marked by a general emergence of the English auxiliary system, and this development is much in evidence in the Wh-questions children ask. However, children do not use auxiliary verbs in quite the English manner. They ask, for example, *what he can ride in?* or *why he don't know how to pretend?* An adult would put these questions differently: *what can he ride in?* or *why doesn't he know how to pretend?* Both the child and adult versions have a Wh-word in the initial position of the sentence, but the child version does not invert the order of auxiliary verbs and subjects. Children do not invert the order of subject and auxiliary in Wh-questions

even though they do invert these same elements in yes-no questions. Along with *what he can ride in?* children also say *can he ride in it?*

Brown et al. (1968) take the different treatment of Wh- and yes-no questions to mean that children perform just one major transformation per question, even though they have more than one appropriate transformation available. In yes-no questions, only inversion of subject and auxiliary is required, and it is performed. However, in Wh-questions, both inversion and a transformation called "preposing" are required, and children perform only the latter.

Preposing refers to one of the transformations in Klima's (1964) and Katz and Postal's (1964) grammar for Wh-questions. In this analysis, the derivation of a Wh-question begins with a deep structure that contains, in effect, a blank for the constituent being questioned. The deep structure of *what can dinosaurs eat?*, for example, is roughly *dinosaurs can eat Δ*, where Δ stands for the NP about which information is sought. One relation between the deep structure *dinosaurs can eat Δ* and the surface structure *what can dinosaurs eat?* is therefore preposing Δ, the result of which is *Δ dinosaurs can eat*, morphophonemic rules then convert Δ to *what*. A second relation between the deep and surface structures of *what can dinosaurs eat?* is inversion of *can* and *dinosaurs*.

Since children say *what dinosaurs can eat?* in the third stage of development, it appears that they do not perform the second transformation when they perform the first. *What dinosaurs can eat?* is an example of what

Brown et al call a "hypothetical intermediate"—a structure defined by the grammar of adult English only at an intermediate stage of derivation

The account of Brown et al assumes that the transformations correspond to actual operations in the production of sentences, it is because of such correspondences that psychological complexity is reduced by eliminating transformations. Some might object to this assumption (see Fodor and Garrett, 1966, 1967). Nonetheless, evidence from a number of experiments with adult subjects shows that transformations do indeed contribute to the psychological complexity of some sentences, at least where the transformation is associated with a change in meaning, although it is far from clear how such effects are brought about (e.g., Miller and McKean, 1964, McMahon, 1963, Gough, 1965, Mehler, 1963, Slobin, 1966c, Savin, and Peichonock, 1965). It is possible, though not yet demonstrated, that a similar relation between psychological and linguistic complexity holds for small children.

However, there is a problem of a different kind. Children always eliminate the same transformation. Children never say, for example, *can he ride in what?* or *will the other Joe drive where?*—questions in which subject-auxiliary inversion has occurred but preposing has not. If children actually reduce complexity by eliminating one of two generally available transformations, it would seem that both types of Wh-questions must occur in a large sample of utterances.

One way to explain the presence of *what he can ride in* and the absence of *can he ride in what?* is to assume that the underlying form of the Wh-questions of the third stage is not yet the adult form—in particular, that the vacant constituent Δ is not in the object position of sentences. In that case there would be nothing to prepose, and a transformation for preposing would not exist. As in the second stage, Wh-words in the third stage would instead be added to the beginning of sentences and therefore invariably appear there. *What + he can ride in* is a possible question under this arrangement, whereas *can he ride in + what* is not.

However, this suggestion also encounters a difficulty. If different Wh-words are introduced at the beginning of sentences, it is

puzzling that such questions are semantically appropriate. The Wh-questions of the third stage are semantically appropriate, however, a fact that demonstrates an association of Wh-words with particular sentence-constituents and (in contrast to the consistent omission of subject-auxiliary inversion) suggests the existence of a preposing transformation. The contradiction only deepens when we recall that the Wh-questions of the *second* stage, when even Brown et al agree that Wh-words are introduced at the beginning of sentences, also are semantically appropriate.

How could appropriate Wh-questions be derived, if not by preposing? Perhaps the contradictory indications just mentioned can be resolved through a more careful scrutiny of the status children give to questions. Klima and Bellugi (1966) list the following answers of children to Wh-questions asked by adults. All are from the second stage.

Adult	What d'you need?
Child	Need some chocolate
Adult	Who are you peeking at?
Child	Peeking at Uisula
Adult	Who were you playing with?
Child	Robin
Adult	What d'you hear?
Child	Hear a duck

Every question is answered appropriately from a semantic point of view. However, in every example except one, the child's answer is a full VP instead of the NP customary in English. A semantically appropriate reply appears in an unusual syntactic setting, one which makes clear that *what* and *who* are not associated with NP alone.

Let us suppose that *what* has as part of its lexical entry a feature such as [+ common noun], that *who* has [+ proper noun], and that *why* has both [+ common noun] and [+ proper noun] as two options. Whenever one of these Wh-words is heard in an adult question, nouns of the specified type are given in reply. Let us also suppose that each Wh-word is understood as a kind of introductory word for an entire sentence, and not as a replacement of a constituent of a sentence as in adult grammar. Then a child's answer to an adult Wh-question will be a sentence that contains an N of a type specified by the Wh-word, it will not be a noun

or verb phrase. Moreover, a child's own Wh-questions will be declarative sentences with Wh-words before them. Children with such a grammar can ask semantically appropriate Wh-questions and not have to prepose Wh-words while doing so.

The facts almost fit this explanation. As expected, a child's own Wh-questions in the second and third stages are generally sentences with Wh-words before them, it is for this reason that subject-auxiliary inversion does not occur in Wh-questions. But the explanation also leads us to expect that a child's answers to adult Wh-questions are sentences, whereas the answers actually given in the second stage are VPs.

However, there is a natural explanation of the VPs of the second stage. A child answers an adult Wh-question with a sentence that includes the material specified by the Wh-word, but he omits the redundant subject of the sentence. Omitting redundant subjects, of course, is a common occurrence in sentences with intrinsic predicates, especially when the subject makes first-person reference. The omitted subjects in the child answers given above are all the pronoun *I*.

In the third stage of development, children answer adult Wh-questions with NPs, as is customary in English (Brown et al., 1968). Doing so, however, contradicts the tendency of children at the same stage to ask Wh-questions by placing a Wh-word before a sentence. There is no process in child speech, corresponding to the omission of subjects, which systematically reduces complete sentences to NPs. However, such contradictions are not peculiar to Wh-questions. As has been widely noted, children often comprehend syntactic forms before they produce them (e.g., Fraser, Bellugi, and Brown, 1963; Lovell and Dixon, 1965), and such apparently is the case here.

The third stage of development is transitional. Children understand Wh-words in the speech of adults as representing particular constituents, but children do not yet produce Wh-questions this way. McNeill (1966a) offers some speculation on the cause of the gap between the production and comprehension of speech—essentially, that the constraints of memory are less in comprehension than in production.

The Role of Adult Speech

One major interaction that takes place between a child's linguistic abilities and his linguistic experiences is localized in the acquisition of transformations. A large part of the problem of understanding language learning is precisely the problem of understanding how this step is taken. In this, the final section on syntax, we shall consider what can be said of the process of transformational development.

Imitation. Imitation has already been mentioned but can be considered again in the present context. There is no reason in principle why imitation cannot be used as a strategy for discovering transformations. By imitating the surface forms of adult sentences, children can pair well-formed surface structures with deep structures of their own devising, and so notice how the two are related. Situational cues might suggest particular deep structures, so the method need not proceed blindly. However, the potential usefulness of imitation is confronted by another principle, which, in actual practice, dominates it. Children systematically convert adult sentences into forms allowed in their own grammatical system. The consequence is that even though deep and surface structures are paired through imitation, the only structures paired in this manner are ones related by rules already known. Apparently children always assimilate adult models into their own grammars, imitation thus plays no role in the acquisition of new transformations.

Expansions and "Prompts." One way to avoid the problem of assimilation is to place the burden of introducing new surface forms on adults. In that case, assimilation to child grammar cannot occur. Brown et al. (1968) discuss two situations that have such an effect, one they call "expansion" and the other "prompting." The effectiveness of the first is open to dispute and the usefulness of the second is so far unknown, but both at least illustrate some of the possibilities that exist.

An expansion is an imitation in reverse. An adult, imitating a child's telegraphic sentence, typically adds to the child's sentence the parts he judges the child to have omitted. The result is an expansion. There is always a number of possibilities available as expan-

sions, and an adult will choose the one that he believes best expresses the child's intended meaning *That mommy hairband*, for example, could be expanded in many directions—*that's mommy's hairband*, *that was mommy's hairband until you dismantled it*, *that looks like mommy's hairband*, etc. Usually one sentence will best fit the extralinguistic situation, and that sentence becomes the expansion.

An expansion that fits both a child's utterance and the extralinguistic situation can reveal one or more transformations. Further, if the child's meaning is correctly guessed from the extralinguistic situation, the expansion presents a surface structure that expresses the deep structure the child has in mind. The expansion is necessarily experienced by the child in contiguity with his intended meaning, and it is effective when the child notices the way the two are related. In this case, there is no intrusion of a child's tendency to assimilate adult speech to his own grammar.

Cazden (1965) looked into the effectiveness of expanding child speech by deliberately increasing the number of expansions given to a group of children. The children were 2½ years old, from working-class homes, spent each weekday in a nursery school, and received in the normal course of events few expansions either at school or at home. In Cazden's experiment every child spent ½ hour a day, 5 days a week, looking at picture books with an adult who systematically expanded everything the child said. At the beginning and at the end of the experiment, 3 months later, the children were given a specially devised test of linguistic performance (covering, for example, NP and VP complexity and the imitation of various syntactic forms).

These expansion children were compared to two other groups of children, taken from the same nursery school, who received in one case what Cazden called "models," and in the other case no special treatment at all. "Modelling" was commenting. Everything said by a child in the modelling group was commented upon rather than improved upon through expansion. If, for example, a child said *doggie bite*, an expansion might be *yes, he's biting*, whereas a model might be *yes, he's very mad*. Children in the modelling

group also spent ½ hour a day, 5 days a week, looking at picture books with an adult.

The results were clear-cut. Relative to the group of children who received no special treatment, there was a modest gain in linguistic performance among the children who received expansions, and a large gain among the children who received models. Cazden interpreted her results by pointing to a difference in the variety of syntactic and lexical forms required for expanding as compared to modelling child speech. In expansion an adult is closely led by a child—he must use the child's words and something like the child's syntax. The opposite is typically true of modelling—he must avoid the child's words and often his syntax. Apparently therefore constraint by a child's own utterances is not beneficial to linguistic development. However, it is this very fact that presumably makes expansion advantageous, clearly, if Cazden is right, the theory of expansion is wrong.

Cazden's experiment shows beyond doubt that modelling benefits linguistic development. However, it is less clear what it shows of the relative benefits of expanding. The rate of expansion of the speech recorded of middle-class children is about 30%. One can ask why this rate is not higher—say 50 or 70%. There must be many reasons why the rate of expansion stabilizes where it does, but one reason is particularly significant: not everything said by a child has an unambiguous meaning in the extralinguistic context, and in such ambiguous circumstances adults tend not to expand.

In Cazden's experiment, on the other hand, the rate of expansion was 100%, by design. Aside from the possibility that young children might not pay attention to many expansions in the face of an avalanche of expansions (Brown et al., 1968), some utterances in Cazden's experiment must have been inappropriately expanded. In such cases a child could formulate a "transformation" that does not belong in English—for example, one that relates the meaning of "that's mommy's hairband" to the surface structure of *that looks like mommy's hairband*. If such misinterpretations took place, the poor showing of expansion in Cazden's experiment is to be expected even on the excessively strong assumption that expansions are decisive in the

acquisition of transformations. The question of the effectiveness of expansion therefore remains open.

Brown et al. (1968) have recently looked at the matter in another way, and again obtained negative results. However, once again counterarguments can be offered in defense of expansion. As noted before, Brown et al. calibrate the linguistic development of their subjects against the mean length of utterances, rather than, as usual, against chronological age. When the calibration is done against utterance length, the rate of advancement of the three subjects in Brown's study is (in declining order) Sarah, Adam, and Eve. When the calibration is against chronological age, the order is Eve, Adam, and Sarah. These orders of development can be compared to the order of expansion by the children's parents. In this case it is Adam, Eve, and Sarah. In other words, Sarah, who is most advanced relative to utterance length, received the fewest expansions.

However, one can dispute the choice of baseline by Brown et al. At any given utterance length, the least advanced child, Eve, used fewer modal verbs, inflections, prepositions, articles, and other superficial sentence-forms than did Sarah, the most advanced child. Length for Eve was increased with content words—nouns, verbs, and adjectives. Thus Sarah's speech was syntactically more like adult English at any given length but Eve's was more informative, as Brown et al. point out. Sarah might have said *that's mommy's hairband*, a well-formed sentence five morphemes long, whereas Eve might have said, semigrammatically, but with the same length, *that mommy broken hairband there*.

Cazden (1967) concludes from the differences between Eve and Sarah that Eve's intellectual development was greater than Sarah's. A difference between Eve and Sarah in intellectual level may well exist, and comparisons of children on syntactic complexity relative to mean utterance length is one appropriate way of demonstrating such a fact—at every point, Eve had more to say but Sarah said it better. Such comparisons, however, do not bear on the alleged role of expansions. This role is to facilitate the acquisition of transformations. A child who receives more

expansions has more opportunities to observe relations between deep and surface structure and therefore can formulate relations sooner. An appropriate baseline against which to measure this effect is chronological age. And relative to chronological age Eve's linguistic development is far in advance of Sarah's.

The role, or lack of role, of expansion in linguistic development is thus open to dispute. The one experiment done on the phenomenon has an ambiguous outcome. The evidence of recorded adult and child speech can be interpreted in diametrically opposite ways, depending on the baseline of comparison.

"Prompting" is discussed by Brown et al. as a possible training variable, but its effectiveness is yet to be investigated. As noted earlier, one transformation in the derivation of Wh-questions in English is a preposing of Δ to the head of a sentence. *Dinosaurs can eat* Δ becomes Δ *dinosaurs can eat*. In a "prompt" something very much like preposing is demonstrated to a child.

A prompt begins with a Wh-question from an adult—*what did you eat?* If a child does not answer, the question may be repeated in a different form—*you ate what?* The second version differs from the first in several respects, one being that preposing has not occurred. If a child understands the second question, and so has in mind the deep structure *you eat* Δ , he is in a position to observe the relation of this deep structure to the surface structure of *what did you eat?* The relation is preposing, and for a child who has not formulated the transformation, a "prompt" may provide an occasion to do so. Brown et al. note that children usually answer non-preposed questions, so prompting is at least potentially effective in revealing preposing to a child.

Brown et al. describe a third parent-child exchange, "echoing," which also can be mentioned although it probably does not provide an opportunity for children to learn a transformation. An "echo" begins when a child's utterance is in part unintelligible—for example, *I ate the gowish*. An adult may then echo the child but replace the unintelligible part with a Wh-word—*you ate the what?* The form of the adult question is the same as in prompting. However, even if a child understands the adult question he could not discover preposing, for that relation is nowhere

revealed. The only relations available in an echo are, on the one hand, between the deep structure *you ate Δ* and the surface structure of *you ate the what?* and, on the other hand, between *you ate Δ* and the surface structure of *I ate the gowish*. If a child recovers the deep structure of *you ate the what?*, he already understands that relation, if he notices the relation between *you ate Δ* and *I ate the gowish*, he observes the relation of a question to an answer. Echoing might tell a child something about answering questions therefore, but it cannot teach him about preposing. Echoing might also help a child discover what in his own utterance belongs to a single sentence-constituent (Brown et al., 1968), the *what* of *you ate what?*, for example, replaces an NP in the child's sentence, the *where* of *you got it where?* replaces a locative adverbial, etc.

A General Condition for Learning Transformations. Both expansions and prompting have in common an ability to demonstrate transformational relations, echoes, on the other hand, do not have such an ability. There are no doubt other exchanges between parents and children that reveal transformations, and it is helpful in the search for such exchanges to isolate the condition that all must meet. In order for a child to observe a transformational relation not yet part of his linguistic competence, he must have in mind the deep structure of a sentence obtained from the speech of someone else, a structure that can only be in a child's mind must coexist with another structure that can only be in the speech of an adult. Expansions, prompts, and imitation meet this demand, but echoes, talking to oneself, rote practice, and many utterances simply overheard by children do not (McNeill, in press). The effect is to reduce even further the effective size of the corpus on which all language acquisition is based.

Such situations as expansion or imitation, which potentially combine a child's deep structure and an adult's surface structure, may not, of course, result in the discovery of transformations. In the case of imitation discovery is systematically blocked by a contradictory tendency to imitate in terms of a child's own grammar. The usefulness of expansions and prompts, while not systematically blocked, depends on a child actually noticing that both a deep and surface struc-

ture are available. Children may not always do this.

Languages differ hugely in their surface structures, they also differ hugely in the transformations that relate surface structures to deep structures. However, there is a small number of universal transformational relations. One transformation discussed in the Appendix permutes the order of verbs and affixes in developing an auxiliary verb. The relation of permutation is universal. Besides permutation, the addition of elements (as in the English passive) and the deletion of elements (as in the English imperative) are universal transformational relations. So is the requirement that deletions from the deep structure be recoverable (forming, e.g., English relative clauses to be made up of constituent and matrix sentences with identical NPs, see Appendix). There may be a few other relations universal in scope, but their total number probably is less than the number of fingers.

Universal transformations may play a crucial role in language acquisition, for it is possible that they describe relations to which young children are innately predisposed. Indeed, that would be at least one reason why they are universal.

If indeed the acquisition of transformations proceeds through the formulation and refinement of hypotheses, the hypotheses apparently take the most general form possible. Children are not cautious theoreticians. They do not, for example, attempt to find an integrating principle that covers two or three local observations, to which they add the results of other small theories devised elsewhere—that is, they do not follow the model of a systems engineer. They are more like theologians in this respect, as their goal is to find hypotheses with the largest possible scope and the fewest possible exceptions. The consequences are visible throughout language acquisition—in inflectional imperialism, in the differentiation of grammatical classes, in negation, and in Wh-questions.

It is possible that the systematization carried out by children can itself be described in terms of a regular principle. The so-called simplicity metric of linguistic theory (e.g., Halle, 1964b, Katz, 1966) is designed to select the simplest grammar that fits both the rest of linguistic theory and the intuitions of

native speakers. Children, in extending linguistic hypotheses to cover different cases, may act in a manner described by such a simplicity metric.

It is worth considering the possibility that children cannot avoid formulating hypotheses about language. Given any kind of linguistic experience, children very quickly develop rules that cover the experience. A few instances of an NP and a VP becoming a sentence may lead to the hypothesis that all sentences are NP-VP constructions. The tremendous generality of children's first grammars suggests the existence of such a phenomenon throughout language acquisition. Generalizations appear immediately. What requires time and further experience is the modification of these generalizations. Language acquisition thus appears to be the opposite of concept formation, where strategies for organizing information lead to the discovery of rules (Bruner, Goodnow, and Austin, 1956). Indeed it is different from most forms of learning studied by psychologists.

The starting-point of grammar is more or less the same for all children, a good deal of space in the preceding pages has been devoted to describing this initial condition. Being universal, child grammar is not the grammar of any language, but is instead something that can become the grammar of any language through a process of formulating and modifying linguistic hypotheses.

In so evolving, language for a child moves from a maximally diffuse to a maximally articulated state. It starts with an intimate and extremely general relation between sound and meaning, it progresses from there to a less intimate and general relation mediated by deep structures, eventually it arrives at the complex and systematic relation between sound and meaning that comprises a transformational grammar. Such is the sequence of events that has been traced in these pages.

The events described in the preceding sections of this chapter take place for the most part before age 4½. At one point it was thought that all of syntax was acquired by this age (McNeill, 1966a, Slobin, 1966a). However, it is now clear that some aspects of syntax are not acquired until much later, and for some speakers certain details of grammar may never be acquired.

C.S. Chomsky (1968) has reported a num-

ber of interesting observations bearing on these questions. She was interested in how children older than 5 understand sentences that depart from what she calls the "minimum distance principle" (MDP). The MDP is a general characteristic of English predicate complements, a type of embedding. *John required Mary to be an enthusiast*, for example, is a predicate complement to which the MDP applies. In such sentences the subject (*Mary*) of the complement (*to be an enthusiast*) is the first NP to the left. This rule is the MDP, and it applies to the vast majority of English sentences. However, there are a few exceptions. In *John promised Mary to be an enthusiast*, the MDP does not apply, for the subject of the complement is *John*—the second NP to the left. *Promise* is one of a small number of exceptional English verbs where the MDP is required not to apply. Another such verb is *ask*. Compare *I asked Mary what to do about the enthusiast* to *I told Mary what to do about the enthusiast*. In the second the subject of *do* is *Mary*, as required by the MDP, but in the first it is *I*.

Sentences with *promise* or *ask* are more complex than sentences with *know* or *tell*. To understand them a child must not only be able to recognize that the complement has a hidden subject but also that the subject is—in contradiction to a general rule—the first NP of the main clause. Inasmuch as children strive to formulate general rules we would expect them to apply the MDP before they discover the exceptions to the MDP. When instructed to "ask Mary what to feed the doll" a child who knows the MDP but not that *ask* is an exception should say something like *what are you going to feed the doll?* Similarly, if asked who will do the feeding in *John promised Mary to feed the doll*, a child who knows the MDP but not that *promise* is an exception should say *Mary*. Such confusions are exactly what Chomsky found.

The course of acquisition is interesting. In the case of *promise* all children above 5 know about the MDP. Some as young as 5 also know that *promise* is an exception to the MDP, whereas others as old as 10 do not. There seems to be no age at which all children discover that *promise* requires the MDP to be violated. A similar history exists for *ask*. Again there is no age at which all children acquire full knowledge of how to use

the verb. Some as young as 5 never make mistakes, others as old as 10 always make mistakes. The situation with *ask*, however, is more complicated than with *promise*, because at first children interpret *ask* as *tell*. In response to the instruction "ask Mary what to put in the box" a child may tell Mary what to put in the box—a doll, for instance. In this case the MDP is applied, but because the child has interpreted *ask* as *tell* there is no reason it should not apply. Only later do children actually ask a question when instructed in this way, and then it is possible to observe incorrect applications of the MDP—"what are you going to put in the box?"

The scattered acquisition of *promise* and *ask* stands in sharp contrast to the acquisition of a third grammatical feature. In sentences such as *after he got the candy Mickey left* and *Mickey thinks he knows everything*, the pronoun *he* is ambiguous—it could be "Mickey" or it could be someone else. Pronouns generally have ambiguous referents in English sentences. However, when the pronoun appears in a main clause and the main clause precedes a NP there is no ambiguity—the pronoun must refer to some other NP. In *he found out that Mickey won the race*, for instance, he cannot be "Mickey." Chomsky studied the acquisition of this "non-identity" rule for pronouns (a study of pronominal ambiguity has been carried out by Chai, 1967, who found children of 10 unable to resolve ambiguous usages). Like *promise* and *ask*, the nonidentity rule is an exception to a general case. Unlike the verbs, however, the absence of ambiguity of the pronoun is itself the result of a grammatical rule. *Promise* and *ask* are exceptional words, pronouns in clauses before NPs are parts of exceptional structures. In contrast to the scattered acquisition of *promise* and *ask*, Chomsky found a discontinuity in the acquisition of the non-identity rule. All children were in possession of it by age 5½, and none were in possession of it before. The difference in acquisition probably has something to do with the difference in the underlying grammatical situation. Rules might be acquired at uniform ages, whereas lexical information is not.

SEMANTICS

Semantic development is at once the most pervasive and the least understood aspect of

language acquisition. It is pervasive because the emergence of a semantic component in a child's grammar has repercussions in wide areas of cognition beyond language itself. It is little understood because there has as yet been little guidance from linguistic theory on what to expect. However, theories of semantics are currently under active development, and matters in this quarter may soon improve (see Katz and Fodor, 1963, Katz and Postal, 1964, Katz, 1966, 1967, Weinreich, 1963, 1966).

The level of sophistication in the study of semantic development is not comparable to the level in other aspects of linguistic development. It differs from syntax, where by now several investigations of language acquisition have been carried out under the general, if not the specific influence of contemporary linguistic theory. And it is diametrically opposite from the situation in phonology: in semantics there are huge quantities of data, but no theory to say which are relevant; in phonology there are almost no data, but there is a theory to say what relevant data would be like in the event they should be collected.

The treatment of semantics that follows will concentrate on a few topics—the development of semantic "features," semantic influences on syntax, the association of semantics with action, and the exchange of information among children. The topics have been chosen in part because of their general interest and in part because they bear on certain theoretical issues.

Studies mainly of a statistical or normative nature are not included. Such studies mostly have to do with children's word associations (e.g., diVesta, 1964a, 1964b, Riegel, 1965b, Riegel and Feldman, 1967, Riegel and Zivian, 1967), and children's ratings on the semantic differential (e.g., diVesta, 1966c, diVesta and Dick, 1966, Rice and diVesta, 1965). Extensive norms of children's free word associations have been published recently by Entwistle (1966), and of children's restricted associations by Riegel (1965a). diVesta (1966a) has published norms of children's semantic differential ratings.

Also omitted are studies of children's cognitive development, including those that deal with the role of language. The reader should consult other chapters in this book for re-

views of this work. See also Bruner, Oliver, and Greenfield (1966) for a summary of recent research on the topic.

For summaries of work on vocabulary development and the development of reference, see previous editions of this book, Brown (1958), and, from a special point of view, Werner and Kaplan (1951).

Semantic Features

It is clear that children have some kind of semantic system at a very early point in linguistic development.

Children at first use words holophrastically. One way of viewing this phenomenon is to conceive of the earliest semantic system as consisting of a dictionary in which words are paired with sentence-interpretations. Each interpretation embodies a particular predicative relation, each word is paired with several interpretations. A holophrastic dictionary of this kind is burdensome for a child's memory and susceptible to ambiguity. The ambiguity can be reduced by the creation of a new dictionary in which words are paired with single sentence-interpretations. However, such a one-to-one dictionary is even more burdensome on memory, as each word must be entered several times, and it too must be abandoned. The ultimate solution is a word dictionary. A word dictionary has the same effect as a sentence dictionary, but not the same bulk (Miller, personal communication).

Both these hypothetical transitions effects a reworking of a child's semantic system. Of the two, however, the second is by far the most significant, and it is from the point of the first construction of a word dictionary that we can date the rudiments of a system basically similar to adult semantic competence (see Katz and Fodor, 1963). In changing from a holophrastic to a sentence dictionary, a child continues to store undifferentiated semantic information, the definition of one sentence is not related to the definition of any other. In changing from a sentence dictionary to a word dictionary, on the other hand, a fundamental modification is introduced in the format of the dictionary entries themselves. A child begins to elaborate a system of semantic features, and sentences come to be interrelated through semantic rules for using dictionary entries.

The evidence is that the accretion of se-

mantic information, in contrast to the acquisition of syntactic information, is a slow process not completed until well into school age. It is the development of a word dictionary that is emphasized in this section.

A child's first effort to compile a word dictionary presumably does not occur earlier than his use of base-structure rules in the construction of sentences. It is difficult to conceive of a word dictionary that does not receive input from some sort of syntactic component, without such input, a word dictionary would result in a loss of power to encode sentence meaning. If one cause of the transition to a word dictionary is a need to retain sentence meaning while reducing the load of a sentence dictionary on memory, compilation of a word dictionary ought not to begin before the first sign of a base-structure grammar, at about 18 months. This sets a lower bound on the beginning of a true semantic component of grammar.

Setting an upper bound is more difficult. Children could continue to use a sentence dictionary after becoming able to construct grammatically organized sentences. Each construction would be referred to the dictionary to learn its meaning. However, such an effort must end when the variety of sentences becomes at all large, as when transformation rules come to be used. A sentence dictionary coupled with transformations requires storing the same sentence-meaning in many places, once for each transformation of the same deep structure. The result would be a large increase in the size of the dictionary. On the other hand, transformations can lead to a reduction in dictionary size if the dictionary is a word dictionary. A word dictionary therefore is favored (in two ways) by the development of transformations, so we can set an upper bound for the first compilation of a word dictionary at the time transformations appear in abundance, at about 28 to 30 months.

We can only guess how the compilation of a word dictionary is carried out. A simple assumption is that semantic features are sequentially added to dictionary entries. Such an assumption is no doubt incorrect in its simplest form. It ignores, for example, the possibility that features are related to one another, and so may enter a dictionary together (Katz, 1966). Nonetheless, a sequen-

tial accretion of semantic features is plausible as an initial hypothesis.

Consider a purely hypothetical example. An entry for the word *flower* would have to include at least the following: a syntactic feature [common noun], several semantic features, perhaps (physical object), (living), (small), (plant), plus certain selection restrictions. An adult dictionary contains more than four semantic features for *flower*, but the ones given are a minimum set. The assumption that dictionary entries are built up sequentially means that the semantic features (physical object), (living), (small), (plant) are added one at a time, though not necessarily in the order listed.

The addition of each feature is an event with widespread consequences. By definition, semantic features appear in more than one dictionary entry, in some cases—the feature (small), for example—a feature appears in a great many dictionary entries. Each new semantic feature is a distinction that separates one class of words from another, a fact that may contribute to the apparently slow manner in which such additions to a dictionary take place.

If the compilation of dictionary entries is sequential, words can be part of a child's vocabulary but have semantic properties different from the same words in the vocabulary of an older child or adult. Semantic development in this case consists of completing the dictionary entries of words already acquired, as well as the acquisition of new words. Simple vocabulary counts miss this internal aspect of semantic development entirely, and in this respect give a misleading picture of linguistic advancement.

Semantic Anomaly. One consequence of the sequential enrichment of a word dictionary is that sentences regarded as anomalous by adults and older children will be regarded as acceptable by younger children. Every dictionary entry contains a set of "selection restrictions" (Katz and Fodor, 1963), which set forth information about a word's allowable contexts. The selection restrictions of a word consist of those semantic markers that can appear as context for the word. A semantic marker in one of the senses of *crane*, for example, matches the selection restrictions of *construction*, so we can have *construction crane*. However, none of the semantic markers

of *construction crane* matches the selection restrictions of the predicate *laid an egg*, so we avoid as anomalous *the construction crane laid an egg*, even though we accept *the crane laid an egg*.

A child who lacks knowledge of some semantic features of a word will accept grammatical combinations that an adult, with a fuller dictionary entry, marks as anomalous. A child accepts anomalous combinations when the features and selection restrictions responsible for the anomaly are missing from his dictionary. If we think in terms of distribution classes—that is, in terms of words that can appear in the same contexts—we can say that a child has distribution classes wider in scope than those possible for an adult. The result of adding semantic markers is a narrowing of distribution classes and an increased tendency to reject as anomalous once accepted word-combinations.

Miller and Isard (1963) performed an experiment in which adult subjects listened to three different kinds of verbal strings through a masking noise. The strings were fully grammatical sentences (*the academic lecture attracted a limited audience*), or anomalous sentences (*the academic liquid became an odorless audience*), or scrambled strings (*liquid the an became audience odorless academic*). A subject's task was to shadow the strings as they were heard. Since a masking noise randomly obliterated parts of the acoustic signal, the performance of a subject depended on an ability to fill in the obliterated parts by guessing on the basis of what was actually heard: the structure of each string.

At several noise levels, Miller and Isard's subjects shadowed fully grammatical strings most accurately, anomalous strings next most accurately, and scrambled strings least accurately. The difference between grammatical and anomalous strings reflects an ability to exploit the semantic restrictions on word combinations, whereas the difference between anomalous and scrambled strings reflects an ability to exploit syntactic restrictions.

What should we expect of children in this experiment? If a child lacks some semantic features, he will be less able than an adult to guess the words of a fully grammatical sentence partly obliterated by noise. If both a child and an adult heard *ate the cheese*, an adult might guess that the subject of the

sentence was *mouse*, but a child might guess *tiger*. What of anomalous sentences? In this case adults and children should not differ, as the presence or absence of semantic features in a dictionary is irrelevant to the reconstruction of sentences where semantic features and selection restrictions do not match in the first place.

Thus, to the degree that a child lacks knowledge of semantic features, performance on fully grammatical and anomalous sentences should be the same. McNeill (1965) repeated Miller and Isard's experiment with children 5, 6, 7, and 8 years old. The procedure was identical to Miller and Isard's in all respects except that McNeill used less exotic vocabulary and that the task was immediate recall. Children of 5 take so long to respond when shadowing that the test was converted automatically into immediate recall.

The results are summarized in Fig. 8, which shows the percent of complete strings correctly recalled by children of different ages. (The percent of content words correctly recalled shows essentially the same result, although the data are less regular.) The conclusion to be drawn from Fig. 8 is clear: 5-year-olds are less able than 8-year-

Fig. 8 Percentage of strings correctly recalled by children 5, 6, 7, and 8 years old (McNeill, 1965)

olds to take advantage of semantic consistency in sentences. Accurately guessing the obliterated parts of sentences depends on the sentences being constructed in accordance with semantic principles available to the guesser. 5-year-olds evidently depart from the semantic rules of English. Since a lack of semantic markers does not affect the accuracy of guessing the obliterated parts of anomalous sentences, performance with such sentences changes very little between ages 5 and 8, as can be seen in Fig. 8.

A third curve in Fig. 8 summarizes the performance of children with scrambled strings. Accuracy in this case is parallel to, but always worse than, accuracy with anomalous strings. The difference suggests that the ability of children to exploit the syntactic information contained in anomalous strings does not change between 5 and 8, a fact consistent with the slow development of dictionary entries relative to the rapid development of syntax.

In general, one can conclude from this experiment that children of 5 find fully grammatical sentences only slightly superior to anomalous sentences. It apparently makes little difference whether one says to a child *wild Indians shoot running buffaloes* or *wild elevators shoot ticking restaurants*. The sentences are equally remarkable.

The experiment just described revealed a tendency for children to reconstruct anomalous and fully grammatical sentences in the same (inappropriate) way. Poor performance in this case was presumably a matter of poor perception. Turner and Rommetveit (in press) have in addition observed anomalous sentences in the linguistic productions of children—for instance, *the tractor drives the farmer*, *the pony rides the girl*, and *the branch carries the bird*. These sentences were not uttered in play or fantasy; they were mistaken but serious descriptions of pictured scenes—a farmer driving a tractor, a girl riding a pony, and a bird resting on a branch.

The word associations of children also show the effects of incomplete dictionary entries. If stimulus and response are regarded as potentially forming a grammatical unit in word association, children's responses often make syntactically possible but semantically anomalous combinations with their stimuli. *Soft-*

wall, *bright-rake*, and *fast-shout* are adjective-noun combinations given in association by 6- and 7-year-olds, and all are anomalous. Adults rarely if ever respond in this way.

Word associations may be divided into two general categories according to the grammatical relation of the stimulus and response. If the response belongs to a different grammatical class from the stimulus, the association is called "syntagmatic" (Ervin, 1961) or "heterogeneous" (Brown and Berko, 1960). If the response is in the same grammatical class, it is called "paradigmatic" (Ervin, 1961) or "homogeneous" (Brown and Berko, 1960). Both Ervin (1961) and Brown and Berko (1960) noted that young children respond mostly with syntagmatic associations, whereas older children and adults respond mostly with paradigmatic associations. The change from a predominance of one response to a predominance of the other takes place between 6 and 8 years—the same ages at which children come to distinguish anomalous and fully grammatical sentences in the experiment by McNeill (1965).

The coincidence of ages suggests that the shift to paradigmatic responding occurs because of semantic, not syntactic, consolidation. McNeill (1965, 1966d) offered a view of how the shift is accomplished on semantic grounds—essentially, that early "syntagmatic" responses are often actually paradigmatic, but fall outside the grammatical class of the stimulus because of the breadth of the semantic categories available to young children. Entwistle (1966) has found some support for this account in her extensive data on children's word associations. Anderson and Beh (1968), while agreeing that the paradigmatic shift results from some kind of semantic consolidation at 7 or 8, argue instead that syntagmatic associations reflect a basically different and less efficient principle of organization of a child's lexicon than do paradigmatic associations. White (1965) has argued that there is a massive change in the intellectual abilities of children at this age, which affects language and cognition alike.

Why is Semantic Development so Slow?
We have reviewed some evidence for the slow, possibly sequential development of dictionary entries. Word association and the recall of sentences both indicate that children

continue to compile dictionary entries as late as age 8, at least. Semantic development thus stands in contrast to syntactic development, which appears to be complete in many respects by 4 or 5.

Why is there such a difference? There must be numerous reasons, and we can barely guess at them. Nevertheless, a few possibilities come to mind. One certainly is the complexity of the information that is encoded in a dictionary. Another is that developments in a child's lexicon, far more than developments in syntax, depend on achieving a certain level of intellectual maturity. A child capable of saying of 20 wooden beads, 15 white and 5 green, that white beads outnumber wooden beads is also likely to say *Lassie's not an animal, she's a dog*. Presumably it is with reference to semantic development that Piaget (1967) comments, "[intellectual] operations direct language acquisitions rather than vice versa."

A third reason for the slow course of semantic development must have to do with the abstractness of semantic features. There is *nothing* in the superficial form of sentences capable even of hinting at underlying semantic regularities. Unlike syntactic abstractions, which are systematically related to surface structure by means of transformations, the semantic relations between surface and deep structure are unsystematic. No general relation holds between the phonemic form of *school* or *uncle* or *space ship* and the meaning of these words. It is one measure, perhaps, of how little insight we have into the acquisition of word meaning that it should thus seem impossible.

Occasionally, one hears the hypothesis that children acquire semantic knowledge from explicit definition. A parent may say *the zebra is an animal*, from which a child may acquire the semantic feature (animal). Perhaps the slow advance of semantic development is a result of a dependence on definitions, unlike syntax, adults may have to provide explicit instruction in semantics.

This argument is fallacious and is so for a simple reason. The sentence *the zebra is an animal* may indeed serve to introduce the marker (animal) into a new point in a child's dictionary, but it cannot affect his basic semantic competence. Explicit definitions may

work to expand vocabulary, but they are irrelevant to the problem that has been considered in this section—the addition of semantic features to a dictionary. In order for the sentence *the zebra is an animal* to influence the dictionary entry for *zebra*, the feature (animal) must already be in the dictionary entry for the word *animal*. If it were not, the sentence *the zebra is an animal* would be without effect on a child's dictionary. But if *animal* contains the feature (animal), then obviously (animal) is already acquired, and the defining sentence merely locates it in a new entry. Explicit definitions are not the vehicle for enlargement of a child's stock of semantic features.

Not all semantic development is slow. The emergence of various semantic distinctions in negation has already been mentioned. They apparently are fully developed by children of 2½ years. Greenfield (1967) has made a similar analysis of the infant term *dada*, tracing the development of its meaning in the speech of her 11-month old daughter. The relevant semantic distinctions (e.g., male versus female, caretaker versus noncaretaker) had all appeared by the first birthday!

It is clear that only some aspects of semantic organization develop slowly. Negation and the idea of a parent emerge very early. So must many other semantic distinctions. Yet 5-year-olds fail to distinguish anomalous from fully grammatical sentences in McNeill's (1965) experiment and they describe a picture of a girl on a pony as *the pony rides the girl* in Turner and Rommetveit's (in press) experiment. It is a fair measure of our understanding of semantics that we cannot say how the last two examples differ from the first two.

A Method for Discovering Semantic Features. One major obstacle faced in the study of semantic development is a sweeping ignorance of the semantic features of English. Very few features have been isolated, and the procedure for discovering them is difficult and slow (see Katz, 1964, for an example).

Recently Miller (1967) has devised a method, based on word-sorting and cluster-analysis, which yields categories of words not unlike the categories defined by the semantic features of linguistics. The method requires subjects to classify large samples of necessarily written words into self-imposed groups,

Fig. 9. Cluster analysis of some English nouns, data from adults (Miller, 1967)

and cannot therefore be used with young children. However, the results of the method with adult subjects can be used to organize such observations of children as are available.

For example, Miller (1967) found that as nouns *yield*, *exhaust*, *battle*, *kill*, *deal*, *play*, *labor*, *joke*, *question*, *vow*, *counsel*, and *help* fall into the clusters pictured in Fig. 9. Each node in the tree represented in Fig. 9 is taken to represent a particular semantic feature: every word beneath a node possesses that feature, words elsewhere do not. Although one cannot obtain such structures from young children, it is possible to see if children honor the distinctions recovered from adults. Do children distinguish, for example, between *the clown told a joke* and *the clown told a battle*? If they do, we infer that children are acquainted at least with the semantic features defining the two large clusters containing *joke* and *battle*. We can also ask about the narrower distinction between *joke* and *help*. Do children distinguish, for example, between *jokes make everybody laugh* and *help makes everybody laugh*? The method is suggestive and deserves exploration.

Semantic Influences on Syntax. Slobin (1963, 1966) performed an experiment with children of 5, 7, 9, and 11 years, in which the truth of sentences was judged against pictured scenes. A picture might show, for example, a dog in pursuit of a cat. A true sentence describing this picture is *the dog chases the cat*, and a false sentence is *the cat chases the dog*. Slobin presented such true and false descriptions in several syntactical forms, using the familiar transformations of negation and passivization to produce variants. For the picture of a dog chasing a cat the following sentences are available

True

The dog is chasing the cat
 The cat is being chased by the dog
 The cat is not chasing the dog
 The dog is not being chased by the cat

One variable in the experiment therefore was syntactic—simple declarative sentences were compared to negative sentences, passive sentences, and negative-passive sentences. Another variable was the truth or falsity of the description. A third variable was semantic content.

Actually two semantic factors are involved. One is negation, and it in turn appears in two forms. Each sentence, being a description of a picture, invokes negation in the sense called "Existence" by McNeill and McNeill (1968). Also, a subject in judging the truth or falsity of a sentence must react—affirmatively or negatively—to the dimension called "Truth" by McNeill and McNeill. The two varieties of negation were therefore invoked at different points in the experiment. Slobin found negative sentences to be more difficult than affirmative sentences—a result also found by Wason (1965). Slobin also found judgments of false to be more difficult than judgments of true when sentences were affirmative, but to be easier than judgments of true when sentences were negative. The interaction of affirmation and truth reveals a general difficulty in combining affirmation and denial. Slobin's task was relatively easy both when affirmative judgments of truth (in the sense of McNeill and McNeill) were made of sentences that were affirmative on existence, and when negative judgments of truth were made of sentences that were negative on existence, but the task was difficult whenever affirmation and negation had to be combined, either as an affirmation of truth for a negation of existence, or as a negation of truth for an affirmation of existence.

The second semantic consideration is something Slobin called "reversibility." A picture of a dog chasing a cat is reversible. Cats can chase dogs as well as vice versa. Deciding whether a sentence is true or false with respect to such a picture depends on deciding which word—*cat* or *dog*—is the grammatical subject and which the object, and then matching this grammatical analysis to the episode shown in the picture. The difficulty of the

False

The cat is chasing the dog
 The dog is being chased by the cat
 The dog is not chasing the cat
 The cat is not being chased by the dog

comparison should be increased when the superficial and underlying subject and object are not the same—as in passive sentences. Thus Slobin expected, and found, that judgments of truth or falsity were less accurate and took longer with passive than with active sentences.

The problem of verification is simplified, however, with pictures of a second type, called "nonreversible" by Slobin. An example of a nonreversible picture is a girl on a pony. If a child understands that girl is the underlying object of the passive sentence *the girl is being ridden by the pony*, he can correctly judge that the sentence is false without matching the sentence to the picture. The semantic constraint simplifies verification by making a judgment possible on internal semantic grounds. Slobin found nonreversible passives to be judged as accurately and rapidly as nonreversible actives. This result held true of children at every age studied by Slobin.

Thus two semantic effects—negation and reversibility—influence children's ability to verify sentences. Negation, although less complex syntactically than passivization, retards verification more. It is the semantic and not the syntactic effect of negation that dominates. Nonreversibility has even greater impact than negation, for it removes every vestige of passivization as a source of difficulty in verification.

Turner and Rommetveit (in press) report a similar result with reversible and nonreversible pictures. They required children to describe pictures as well as to judge the truth or falsity of sentences about pictures. In production, as previously noted, children often reverse the order of subject and object—say, *the pony rides the girl*. The gains produced by nonreversibility for comprehension thus do not seem to extend to production at the ages studied (4 to 9 years). Describing a picture of a girl on a pony with the sentence *the pony rides the girl* is equivalent to saying that *the girl is being ridden by the pony* is true. But children who commit the first error do

not commit the second in Turner and Rommetveit's experiment

Recent work by Bever, Mehler, and Valian (1967) clarifies the role played by reversibility in these experiments. Bever, Mehler, and Valian's subjects were very young—2 to 4 years, compared to 5 to 11 years in Slobin's experiment. The difference in age makes for an important and surprising difference in outcome. Bever et al. found that the semantic constant of nonreversibility does not help performance at all at 3 years, even though children this young can comprehend some passive sentences more than half the time. By 4 years, however, children's comprehension of reversible passive sentences begins to deteriorate and their comprehension of nonreversible passive sentences correspondingly begins to improve. Children begin at 4 years to perform as in Slobin's and Turner and Rommetveit's experiments. Thus, at first, reversible and nonreversible situations are treated alike when described by passive sentences, later they are treated differently, and children actually retreat from a level of performance previously reached in reversible situations. A similar study by Hayhurst, 1967, also found "young" children not taking advantage of nonreversibility, however, her subjects were older than Bever et al.'s subjects—in fact, the age of Slobin's subjects, 5 years.

Bever et al. argue plausibly that children adopt certain general strategies in understanding sentences—for example, that English sentences are semantically coherent, and that they describe an actor, an action, and an object acted upon. Such semantic strategies depend on a conviction that utterances make sense and on a knowledge of what makes a situation reversible or nonreversible. Information of this kind is distinct from grammatical knowledge—for example, that the underlying relations in a sentence are subject, verb, and object. The semantic strategy is acquired later than knowledge of the grammatical relations among elements, and is derived from a different source—perhaps a statistical predominance in speech of sentences describing actors, actions, and objects acted upon. It is not the same as a syntactic analysis of a sentence. It is, rather, a method, based on semantic coherence, for facilitating a syntactic analysis.

A statement of the strategy, differing slightly (but importantly) from the version described by Bever et al., is as follows:

- 1 Assume that noun-verb-noun stands for actor-action-object
- 2 If this is implausible, assume that noun-verb-noun stands for object-action-actor

Under the influence of this strategy, reversible passive sentences can be construed as active sentences, even though the transformation of passivization is available. *The cat is being chased by the dog* becomes, under the strategy, *cat* (actor) *chase* (action), and *dog* (acted upon). The semantic coherence of a cat chasing a dog leads to a reversal of grammatical subject and object. The same strategy, however, protects a child from a reversal of subject and object in nonreversible situations. *Pony* (actor), *ride* (action), and *gull* (acted upon) must be rejected by a child expecting semantic coherence, so *the pony is being ridden by the gull* is correctly understood as a passive sentence. Young children without a semantic strategy treat reversible and nonreversible situations alike and sentences describing both are open to the same confusions.

The strategy of exploiting nonreversibility is an example of what Jakobson (1960) has called the "metalinguistic" function of language. An expectation that sentences will contain an actor, an action, and an object acted upon is a hypothesis about language. It is comparable to such other hypotheses as, for example, that all words have a rhyme, or that all sentences have a middle. It is different from the linguistic hypotheses considered in the section on Syntax, which comprise the syntactic competence of a child.

The relatively late appearance of a strategy based on semantic coherence probably is related to the insensitivity to semantic anomaly uncovered in McNeill's (1965) experiment; there is, however, a discrepancy in ages.

The Association of Semantics and Action
The strategy mentioned earlier—that sentences contain an actor, an action, and an object acted upon—can take other forms. For example, children following this strategy can use sentences to direct their own activity. They can do so, that is, if the actor in an action and the subject of a sentence directing the action are the same. But if children must

performs an action that violates the strategy, performance becomes disrupted. Such is the conclusion reached by Huttenlocher, Eisenberg, and Strauss (1968) and Huttenlocher and Strauss (1968).

The experiments are elegant in their simplicity. In one (Huttenlocher et al., 1968) a child sees before him a "road" consisting of a flat board divided into three spaces. The middle space already contains a toy truck. The child has in hand a second truck, which he is told to place either before or after the fixed truck. It is the way of telling that counts. Assume that the child's truck is painted green and the fixed truck is painted red. Any one of four possible instructions can then be given: (1) the green truck is pulling the red truck, (2) the red truck is pulling the green truck, (3) the red truck is pulled by the green truck, and (4) the green truck is pulled by the red truck. Another four instructions are available with the verb *push*. In every case, the actor is the green truck the child is holding; it is the one that must be moved. Thus in sentences (1) and (3) the actor and the underlying subject of the sentence are the same, whereas in sentences (2) and (4) the actor is the underlying object of the verb *pull*. Sentences (1) and (3) should therefore be more easily followed as instructions than sentences (2) and (4).

Sentences (1) and (2) are active sentences, whereas (3) and (4) are passive. If children treat the superficial instead of the underlying subject of a sentence as an actor, then sentences (1) and (4) ought to be easiest, and (2) and (3) hardest, as *green truck* is the superficial subject in the first pair and the superficial object in the second pair.

Huttenlocher et al. found the amount of time for 9-year-old children to place the moveable truck correctly increased from sentence (1) to sentence (4). Since (1) < (2) and (3) < (4) it is clear that children associate the subject of a sentence with the actor of an action. This is the strategy discussed by Bever et al. (1967). Since (3) < (4) it is also clear that the underlying and not the superficial subject is the one associated with the actor. Finally, since (2) < (3) it is clear that passivization poses problems of its own; the situation in Huttenlocher's experiment was reversible.

Huttenlocher et al. also discovered a sys-

tematic difference between the two verbs *push* and *pull*. For all four types of sentence, children's reaction time to *push* was faster than to *pull*. In terms of comprehension, at least, a push is not a backward pull.

An experiment by Huttenlocher and Strauss (1968) produced similar observations of children following instructions of the form, *the red block is on top of the green block* and *the yellow block is under the brown block*. A child in this experiment was faced with a ladder, the middle rung of which contained a block, the instruction told him to place a second block above or below the block already fixed in place, the position depending on the color of the block the child had in hand. The instructions were easiest to follow when the actor (the child's block) was also the subject of the sentence. Since there are no passive forms of the sentences used in this experiment, the association of an actor with the underlying subject of a sentence could not be demonstrated.

Bem (1967) has replicated Huttenlocher and Strauss' results in all particulars, but arrives at a rather different conclusion. In the view of Huttenlocher and Strauss, sentences such as *the red block is on top of the green block*—when a child is holding a green block—are difficult because the sentence must be changed into one where the child's block is the grammatical subject—*the green block is under the red block*. The extra step takes its toll in time. In Bem's view, the problem facing a child is not to perform a linguistic operation, but to imagine a situation in which the sentence as given is a true description. Again the extra step takes its toll in time. Whereas in Huttenlocher and Strauss' view a *sentence* must be transformed, in Bem's view a *situation* must be transformed. In order to distinguish the two interpretations, Bem asked her subjects to describe the tower of blocks they had made. If subjects first had to transform the sentence to make the tower, the transformed sentence ought now to appear as a description. However, 90% of Bem's subjects used the original untransformed sentence, as if nothing had been done to alter its form.

Many psychologists have assumed that language and action in children are closely associated. Although this sometimes has meant that child language is primarily an expression

of action (see de Laguna, 1927), the regulative function of language has been more often studied (however, see Clark, in press, for evidence that prepositions are at first expressive of movement). The many experiments of Luria (1961, also see Luria, 1959, Birch, 1966) have traced the development of verbal control—that is, the ability of children to follow verbal instructions. The experiments of Huttenlocher et al., Huttenlocher and Strauss, and Bem bear on the same question. The present chapter is not the place to explore the possibility that the emergence of verbal control in children depends on the emergence of the metalinguistic hypothesis that sentences describe an actor, an action, and an object acted upon. However, the matter deserves investigation. Such an exploration presumably would look into a child's knowledge of grammar in relation to his application of such strategies, it is clear that the two are not the same, and the problem arises as to how they are interrelated.

This problem arises with particular acuteness in the experiments described by Luria (1959, 1961). Working within the general framework established by Vygotsky (1962), Luria and his colleagues have traced the development of what they consider to be voluntary action. In the Vygotskian scheme of things a basic continuity exists between the control of one's action by others and the voluntary control of one's action by oneself. All control is a matter of following instructions, either external or internal. Self- or internal control depends on the development of inner speech, and inner speech in turn derives from socialized speech. Self-control is therefore preceded genetically by external control.

To very young children, commands are simply occasions for action. The speech of others triggers an action a child is ready to perform. A child who has repeatedly been made to retrieve a coin beneath an inverted cup will still search under the cup when told to find a coin under a nearby glass. The specific property of the instruction—that it contains the word *glass* rather than *cup*—has no effect. The same tendency appears in other situations. Told to press a ball when a light flashes, children younger than 2½ immediately look for the light and press the ball. When the light is subsequently flashed a

child looks at it but ignores the ball. A command at this stage initiates two independent acts that are not put together. Children fail to react to the grammatical structure of the command.

Commands possess for young children what Luria (1961) calls an "impulsive quality." If children of 3 are told *not* to press a ball when a light goes on, they press anyway. Moreover, if they are told to say "don't press" when a light goes on, they still press even while saying "don't press." A 3-year-old child's reaction to his own speech is therefore independent of the content of his speech. Speech is more like a metronome. If told to say "I'll press twice" when a light goes on, a child of 3 presses once and maintains pressure for the duration of the sentence. If on the other hand, he is told to say "go! go!" when the light goes on, he presses twice because there are two impulses. It is not until 4½ or 5 that children react to "go! go!", "I'll press twice," and "don't press" in appropriate ways.

One wonders, in line with the preceding remarks, if the change at 4 or 5 results from application of a metalinguistic strategy that relates the grammatical subject, verb, and object in a sentence to the actor, action, and object acted upon in a situation. Because such a strategy is discovered relatively late in development, children before this point react to commands as if they had no internal structure, but are instead merely external signals to act. However, once a strategy is adopted "the regulatory function is steadily transferred from the impulsive side of speech to the analytic system of elective significant connections which are produced by speech" (Luria, 1961, p. 92, italics omitted).

The Exchange of Information among Children. Piaget (1923) long ago devised an experiment in which children instructed other children on the operation of a mechanical device—a syringe, for example. Children less than 6 are not very good at this. They use gestures and such pronouns as *this*, *that*, *something*, *there*, and *here*—even when the child being instructed is, for example blindfolded. For Piaget, the difficulty of communication arises from the egocentrism of children. The instructor takes it for granted that the other child already knows how a syringe works, since he, the instructor, also knows

how it works. All that must be done in order to communicate therefore is to make reference to common knowledge.

More recently Glucksberg and Krauss, and various of their collaborators (Glucksberg, Krauss, and Weisberg, 1966, Glucksberg and Krauss, 1967, Krauss and Rotter, *in press*, Krauss and Bricker, 1967, Krauss and Weinheimer, 1964, 1966), have looked at the same phenomenon as a matter of communication efficiency. Viewing an exchange of information as a question of communication efficiency is not, of course, incompatible with explaining poor efficiency by reference to egocentrism.

In a typical experiment two children (or adults) are seated on opposite sides of an opaque screen. One is an encoder and the other is a decoder of messages about a set of unusual visual forms. The forms are chosen in advance as ones without readily available names in English, the experiment therefore differs from Piaget's, where vocabulary existed (in fact, was taught) to describe the object.

In general, the success of children's messages to other children is low. Children use shorter descriptions than adults do, and the descriptions are sometimes highly idiosyncratic. Idiosyncratic messages are not meaningless, however, even though they are poor for communication, when children serve as their own decoders, the level of accuracy is relatively high (Glucksberg et al., 1966). Brevity of description is characteristic of adults when the same form has been described several times previously, and arises because messages about familiar things tend to minimize redundancy (Zipf, 1935, Krauss and Weinheimer, 1964). That young children *begin* with such messages possibly reflects the egocentrism discussed by Piaget. It suggests that children differ from adults in their conception of familiarity, egocentrically assuming that every known thing is a familiar thing.

When children are given messages encoded by adults, communication accuracy soars (Glucksberg et al., 1966). An adult will say of a figure that it looks like an "upside down cup." Children respond to this description much as adults do. But children *say* of the same figure that it looks like "mother's dress," "Ideal" (referring to the trademark of a brand of toys), "digger hold," "a caterpillar," or "a ghost." Children are

therefore better at decoding than encoding messages.

Even though children are better decoders than encoders, children as decoders do not treat the communicative messages of adults differently from the noncommunicative messages of other children. All messages are accepted passively and with little comment. Moreover, children as encoders do not modify messages when explicitly requested to do so by adult decoders (Glucksberg and Krauss, *in press*). In these respects children are sharply different from adults, who request and receive new descriptions when a description seems to them insufficiently precise. One of the children described by Glucksberg and Krauss (1967), when told to pick up "this one," asked the child on the other side of the opaque screen "do you mean that one?", the reply was "yes." Although children can understand the messages of adults, they act as if they can understand every other message as well.

Symbol Formation. A review of semantic development would not be complete without mention of the work of Werner and Kaplan (1963). They have attempted to explain certain aspects of language acquisition as a consequence of cognitive development, and so, unlike other cognitive theorists, have confronted the problem of cognition and language.

Werner and Kaplan raise a number of fundamental questions. What are symbols? How do they develop in children? How is language intertwined with action? How does the relation between language and action change with development? It is not surprising, perhaps, that Werner and Kaplan do not provide satisfactory answers to these questions. No one does. But it is ironic in their case that a source of difficulty is a commitment to an analysis of symbolization promoted by the very empiricist philosophers whom Werner and Kaplan are at pains to dispute.

Werner and Kaplan regard the problem of learning the meaning of words as a problem in "distancing." A child must distinguish between himself and the objects to which words refer, he must distinguish between himself and words, and he must distinguish between words and objects. At first speech is held to be limited to onomatopoeia. A child tries to imitate the acoustic qualities of objects. Ob-

jects are not clearly distinguished from a child's own activity, including the activity of imitating acoustic quality, and imitation clearly is something a child himself does. Word, object, and child are therefore fused. In contrast, the words and meanings of adult languages are arbitrarily related to oneself and to objects. To move from such an onomatopoeic beginning to the arbitrary vocabulary of adults, a child must interpose "distance" between himself, words, and objects.

The first step is to transcend the single sensory modality of hearing. Onomatopoeia is necessarily limited to objects that make a noise. Synesthesia rests on a similarity between sensory modalities, and thus provides a means whereby the visual (or tactual or olfactory) qualities of objects also can be vocally imitated. Werner and Kaplan firmly believe that sounds have physiognomic qualities (of which synesthesia is one special type): it is a physiognomic similarity between acoustic and visual perception that causes "zigzag" to be a bad name for a circle and a good one for a jagged line. Through such synesthetic similarities "distance" is first interposed between words and objects. Continuing in this physiognomic direction, a child eventually arrives at the arbitrariness of adult lexicon, by then all outward similarity between words and referents has been lost.

Fodor (1964) has written a blistering critique of this theory. He finds in it an entire catalogue of philosophical blunders. According to Fodor, the theory is "surprisingly conservative", it is "circular", it is "inefutable", it is "doctrinaire", and it is "not scientific". Unlike the classical empiricists, who regarded symbolization as a result of both causation and similarity, and unlike modern learning theorists, who regard it as a result of causation alone, Werner and Kaplan regard symbolization as a result of similarity alone. The key, as noted, is physiognomic similarity.

Sounds and objects are physiognomically similar when they are integrated into similar "postural-dynamic patterns." Since these patterns govern the similarity of words and objects, outwardly the properties of words and objects may differ markedly—and so may appear to be arbitrarily related—but inwardly they are similar. The difficulty with such an argument, as Fodor points out, is

that it is essentially post hoc. The *only* way to find out if a word and an object are physiognomically the same is to find out if the word refers to the object. There is no way in principle to test such a theory.

Fodor's review should be read carefully. It shows the difficulties and hazards of proceeding in the area of semantics. To his critique, perhaps only one thing should be added. As previously noted, Werner and Kaplan are concerned with the problem of cognition and language. Their effort in this direction is unique. However, the relevance of Werner and Kaplan's theory to the problem of cognition and language is quite unknown. Werner and Kaplan take for granted that symbolization is a weak universal—a universal imposed by human cognition. But, for all we know, symbolization is a strong universal—a peculiarity of the human system of communication. There have been no empirical investigations of the distinction.

PHONOLOGY

If semantics is regarded as the basement of syntax, then phonology is the penthouse. It is ironic that so little can be said of the acquisition of this most visible part of language. Little can be said, even though the study of sound has long been a dominant concern of linguistics and an explicit theory of phonemic development has existed for more than a quarter of a century (Jakobson, 1941, 1968). The challenge posed by phonology has never been accepted.

We must distinguish at the outset between phonemic and phonological development. The first refers to the emergence of the sound units of a language, something can be said about phonemic development, and it is here that Jakobson's theory applies. Phonological development on the other hand refers to the emergence of rules for combining sounds into pronounceable sequences in a language and for relating such sequences to the surface structure of sentences. Virtually nothing can be said about this aspect of development.

The Relation of Babbling to Speech. All parents know that children babble during the second 6 months of life. Before that time vocalization is highly limited, and after that time speech proper begins with the appear-

ance of holophrastic utterances During the babbling period children vocalize an immense variety of sounds in ever more complex combinations It is possible that the babbling period is a bridge between the limited vocalization of the first 6 months of life and the appearance of communicative speech itself Such a hypothesis has indeed been proposed Allport (1924) believed that children develop the phonemic system of their native language by matching speech sounds they hear to sounds they produce in babbling Staats and Staats (1963) and Mowrer (1952, 1960) hold a similar view However, it is a view with no basis in fact, there is on the contrary a sharp discontinuity at both ends of the babbling period Babbling, if it plays a part in the emergence of speech, does so far behind the scenes It is not a bridge

The direction of development during the first year of life is from the back to the front of the mouth for consonant-type sounds and from the front to the back of the mouth for vowel-type sounds (Irwin, 1947a, 1947b, 1947c, 1948, McCarthy, 1954, however, see Bever, 1961, for some qualifications) The direction of development during the second year of life is exactly opposite First to appear as *speech* sounds are front consonants and back vowels The back consonants and front vowels that were the first uttered in the period of prespeech are among the last organized into a linguistic system

Children younger than 3 months vocalize such consonantlike sounds as [k], [g], and [x], and such vowel-like sounds as [i] and [u] That is the beginning In the babbling period many more sounds are added—sounds necessarily more forward in the case of consonants and more backward in the case of vowels When linguistically meaningful utterances first occur, however, they consist of a front consonant, /p/ or /m/, and a back vowel, /a/ (Following the usual practice, linguistically significant sounds—phonemes—are enclosed in slant bars and linguistically nonsignificant sounds—phones—are enclosed in square brackets) Front consonants and back vowels provide a starting point for speech regardless of the language to which children are exposed children exposed to English say *tut* before *cut*, children exposed to Swedish say *tata* before *kata*, children ex-

posed to Japanese say *ta* before *ka*, and so on (Jakobson, 1941) The early appearance of /m/ and /p/ as speech sounds is no doubt one reason why *mama* and *papa* are among the first words acquired by all children

The baby talk of adults usually corresponds to this initial phonemic organization Ferguson (1964) found replacement of velar by dental consonants in the adult speech addressed to children among speakers of Syrian, Marathi, Comanche, English, and Spanish An English example is *tum on* for *come on* (phonemically, /kum/) The only exceptions among the languages Ferguson reviewed were Arabic and Gilyak, in both of which velar consonants play a particularly large role Baby talk is conventionalized speech for children In spite of the large differences among the phonemic systems of Syrian, Marathi, Comanche, English, and Spanish, the conventions for baby talk are the same, presumably because actual child speech in each of these languages is organized in the same way

The front consonants and back vowels organized by children into an initial linguistic system also occur in babbling However, many other sounds occur in children's babbling, as well, including the back consonants, [k] and [g], and the front vowels, [i] and [u], which are added to a child's linguistic system only after many months of further development Rather than continuity there is discontinuity Children quickly pass from a wealth of vocalization to concentration on a few sounds for communication It is not a question of selecting some sounds from many, it is rather a question of why the same specific sounds constitute the beginning of every child's phonemic system Intentional vocalization requires a structure that unintentional vocalization does not A child who uses only /p/, /m/, and /a/ in speech will at the same time use [k], [g], and many other sounds in nonspeech (Jakobson, 1941) As Jespersen (1925) remarked,

It is strange that among an infant's sounds one can often detect sounds—for instance, k, g, h, and uvular r—which the child will find difficulty in producing afterwards when they occur in real words The explanation lies probably in the difference between doing a

thing in play or without a plan—when it is immaterial which movement (sound) is made—and doing the same thing of fixed intention when this sound, and this sound only, is required (p 106)

Jakobson's theory of phonemic development is addressed to the sound structure of early speech. However, before discussing his theory, let us look a little more carefully at the period of development before the emergence of speech. Doing so will make more concrete the discontinuity between speech and prespeech.

Prespeech and Neurological Maturation in the First Year of Life There are in fact two discontinuities during the first year of life—one at 4 months and a second at 11 or 12 months. The two together roughly bracket the babbling period. Bever (1961) reanalyzed the extensive data reported by Irwin and his collaborators (Irwin, 1947a, 1947b, 1947c, 1948) in terms of the rate of change in sound development. Irwin transcribed children's vocalizations in the International Phonetic Alphabet, so his data consist of information on a large number of separate phonetic types; in general the data reveal a steady proliferation of phonetic types with age. Bever focused instead on the rates of change of phonetic types and found discontinuities at 4 and 11 or 12 months.

The two discontinuities mark off three periods. The first period, from birth through the third month, consists of a very rapid rate of change in the frequency and variety of vowel-like sounds and a somewhat lower though still rapid rate of change in the frequency and variety of consonantlike sounds. At 4 months, the rate of change drops abruptly, thus ending the first period and starting the second. The second period is a succession of peaks without large intervening troughs. A peak in the rate of change in the variety of vowel-like sounds occurs between 5 and 6 months, then a peak in the rate of change in the variety of consonantlike sounds at 7 months (affecting dental and labial consonants particularly), finally a large peak in the rate of change in the variety of all consonantlike sounds at 9 or 10 months. Then, total collapse at 11 or 12 months. The collapse at 11 or 12 months is the beginning of

true linguistic development, the events it introduces are discussed in the next section.

Bever points to similar cyclical phenomena elsewhere in development (e.g., in the amount of sleep per day) and argues that the episodic advance of vocalization reflects a series of changes in cerebral maturation, particularly of an unfolding pattern of inhibition and integration during the first year of life. The hypothesis is provocative and worth quoting.

The cycles observed in vocal development are produced by phases of neurological maturation. a) The first cycle is concurrent with and presumably a manifestation of a primary level of neurological organization of vocal behavior. b) The end of the first cycle is a result of the end of the reflex stage of behavior due to cortical inhibition. c) The second vocal developmental cycle occurs as the cortex gradually reorganizes the activity it had inhibited.

The difference in the manifest behavioral characteristics of the first and second cycles in vocal development are due to differences between the lower and higher levels of neurological organization. a) There are two essential features of the first cycle of vocal development, and thus of the primary neurological phase, a concern with tonal activity and the primary differentiation of affective crying. b) The second cycle and thus the second neurological phase is associated with the development of consonant-like activity, and is often referred to as the period of "preparation" for the onset of language-learning proper. The babbling stage is presumably a reflection of the process of integrating vocal activity and cortical organization (Bever, 1961, p 47).

So much for prespeech and its alleged connection with the nervous system. We now turn to the beginnings of language.

The Differentiation of Distinctive Features

The name of Roman Jakobson is associated with what is, beyond doubt, one of the most useful concepts in contemporary linguistics. This is the notion of a linguistic feature. In phonemics, where Jakobson developed the idea, linguists speak of distinctive features, but essentially the same insight into language has been invaluable in semantics and syntax,

and previous sections of this chapter have relied on it heavily

It is Jakobson also—in a celebrated paper, *Kindersprache, Aphasie, und allgemeine Lautgesetze* (1941)—who first applied the concept of a linguistic feature to questions of language development. In the same paper, moreover, he presented for the first time a modern conception of the relation between linguistic universals and the development of language. (The general importance of universal grammar had been realized centuries before, see Chomsky, 1966.) Developmental psycholinguistics thus owes Jakobson a considerable debt. It is fortunate that *Kindersprache* has at last been translated into English by A. Keiler (Jakobson, 1968). For a brief discussion of the theory, see Jakobson and Halle (1956), for a general discussion of distinctive features, see Jakobson, Fant, and Halle (1963).

It is remarkable that Jakobson's theory has inspired so few empirical investigations. The few studies that have been conducted, however, support the general line of argument, although not every detail (see Velten, 1943, Leopold, 1947).

The development of a phonemic system, according to Jakobson, is the result of filling in the gap between two sounds, /a/ and /p/. The process of development is differentiation. /p/ is a consonant formed at the front of the mouth, it is a stop, it is unvoiced, and it represents a nearly total absence of acoustic energy. /a/ contrasts with /p/ in each of these respects. It is a vowel, it is formed at the back of the mouth, it results from a complete opening of the vocal tract and it represents a maximization of acoustic energy. One might say that /a/ is an optimal vowel and /p/ is an optimal consonant. Each is an extreme example of its type, and the contrast between them is as large as possible. With this contrast, linguistic development begins on a phonemic level.

However, neither /p/ nor /a/ are phonemes at the outset of development (and thus, strictly speaking, should not be written between slant bars). A phoneme is a meaningless sound used to distinguish meaningful messages. /p/ and /a/ are instead meaningful sounds that distinguish no messages. The consonant always appears with the vowel, and there are only two possible utterances

pa and (with reduplication) *papa*. The meaning of these words may be highly diffuse, and a child may attempt to communicate more than one message with each word, but there is not yet a phonemic system.

In order to establish a phonemic system, the space between /p/ and /a/ must be differentiated. The first such split occurs on the consonant side and (according to Jakobson's observations) results in a distinction between a labial stop /p/ and a nasalized labial /m/. The distinction therefore is between nasal and oral sounds and it creates two words—*ma* and *pa* or (with reduplication) *mama* and *papa*—distinguished by what are now two phonemes, /m/ and /p/. Velten (1943) found the first consonant distinction to be slightly different: labial stops were first contrasted with continuants (/f/ and /s/), and only later with nasals. The nasal-oral distinction thus appeared second in development rather than first.

The vowel /a/ at this stage merely supports the consonants /m/ and /p/, and itself has no phonemic status. However, the vowel plays a crucial role of a different kind, for together with the consonants /a/ establishes a syllable. Syllabification is present from the outset of speech. It is not obvious why such should be the case. Perhaps there is some basic rhythmicity underlying speech, as Lennberg (1967) has argued, which takes as its earliest manifestation syllabification and reduplication. Jakobson (1941) believed that children always formed consonant-vowel (or vowel-consonant) syllables in earliest speech, but apparently this is not invariably the case. Wen (1966) observed Chinese children uttering syllables that consisted of vowels only, although Russian- and English-speaking children also included consonants, as expected. Chinese is a language in which syllabification is measured by vowels alone, whereas Russian and English are not. Wen's findings may reflect the existence of language-appropriate syllabification at an extremely early age.

After the consonants have been divided into nasal and oral categories, there appears a division of oral consonants into labial and dental categories. /ta/ comes to be contrasted with /pa/ (Jakobson, 1941). After this there occurs the first division on the vocalic side. Narrow vowels are set off against wide vowels, as in /pɪ/ versus /pa/. The

next step according to Jakobson may be in either of two directions. One alternative is to divide the narrow vowel into a narrow palatal vowel /pɪ/ and a narrow velar vowel /pu/. The other alternative is to create a high-mid-low vowel series by inserting /e/ between /a/ and /i/, as in /pa/ versus /pe/ versus /pi/.

Jakobson argues that the sequence of phonemic development is invariant and universal among children. All children pass through the same steps, although children may differ from one another in the rate of advancement. Moreover, the phonemic system created by the first two or three steps in phonemic development is universal among the languages of the world: "the child possesses in the beginning only those sounds which are common to the world, while those phonemes which distinguish the mother tongue from the other languages of the world appear only later" (Jakobson, 1968, quotation from the Keiler translation).

There is a striking similarity between phonemic and syntactic development. Both begin with a primitive form that is universal. In both, the starting point is not any particular language, but is so organized that it may become any language through a process of differentiation. Perhaps we should not be surprised at the similarity; the separation of sound and syntax is a scholarly artificiality. In fact, human communication always takes a specific form and it is not surprising that the same basic form appears in all its aspects.

The differentiation of the space between /p/ and /a/ is the result of successively introducing certain distinctive features. Jakobson summarizes the process of development in terms of a series of vowel and consonant triangles (Jakobson, 1941, Jakobson and Halle, 1966).

The first phonemes, /p/ and /t/, together with the optimal vowel /a/, comprise what Jakobson and Halle call the "primary triangle." It defines two distinctive features—

compact-diffuse on the vertical axis and grave-acute on the horizontal axis.

When the vowel /a/ is in turn differentiated into wide (/a/) and narrow (/i/) vowels, the distinction between compact and diffuse is introduced into the vocalic category. Thus, compact versus diffuse no longer sets vowels off from consonants, and we have instead,

If the narrow vowel /i/, which is also palatal, is next distinguished from the velar vowel /u/, which is also narrow, the distinctive feature grave-acute is likewise introduced into the vocalic category. Grave-acute is therefore the first contrast shared by vowels and consonants. It gives rise to the following triangle:

At this point, vowels embody more distinctions than consonants. Balance is restored when the front consonants /p/ and /t/ are distinguished from the back consonant /k/, /p/ and /t/ are diffuse, whereas /k/ is compact. We now have two complete triangles defined by the same features,

The succession of vowel and consonant triangles explains why the first phonemic contrast that children draw is between /a/ and /p/ and not between /a/ and /k/, or

/i/ and /p/, or some other pair /a/ is the most compact of all sounds, whereas /p/ (along with /t/) is the most diffuse. It is on the distinctive feature of compact-diffuse that /a/ and /p/ are the optimal vowel and consonant. To utter /a/ the mouth forms a funnel opening forward, to utter /p/ it forms a funnel opening backward. In the case of /a/ a large amount of acoustic energy is concentrated in a narrow band of frequencies, in the case of /p/ a small amount of energy is distributed over a wide band of frequencies. The sound /t/ is as diffuse as /p/ in terms of the distribution of energy, but it differs less from /a/ in the location of closure of the mouth, and for this reason is not chosen first as the consonant to be set off against the new vowel /a/.

The Development of a Phonemic System and the Laws of "Irreversible Solidarity"
The laws of irreversible solidarity describe universal asymmetries in the phonemic systems of the languages of the world. For example, no language has back consonants without also having front consonants, but languages exist with front consonants and no back consonants. There is an irreversible "solidarity" between back and front consonants such that the former presuppose the latter but not conversely. The laws of irreversible solidarity describe languages (see Greenberg, 1963, 1966, for a number of examples of universals of this kind). Jakobson's (1941) suggestion is that the same laws describe the development of language by children (as well as the loss of language by aphasics). Thus no child arrives at back consonants without first developing front consonants. /p/ and /m/ always appear before /k/ or /g/, for example. Jakobson gives many examples of such an identity between

the order of acquisition and the distribution of phonemes among the languages of the world.

Phonemes that are relatively rare among the languages of the world—for example, the English /θ/ as in "thing"—are the last phonemes acquired by children exposed to languages that contain them. It is as if, when children must push farther and farther from the universal core of language, fewer and fewer languages force them to do so (see discussion of the informal dialect of New York speakers as described in Labov, 1964). In general, rare phonemes embody more distinctions, of a more subtle type, than do phonemes of wider distribution and earlier appearance. If the acquisition of phonemes is the result of differentiation, as Jakobson argues, then phonemes that embody numerous and subtle distinctions are naturally acquired after phonemes that embody less numerous and subtle distinctions. A natural order of acquisition and distribution therefore results from the latent but universal structure of distinctive features. Jakobson (1941) argues that the structure inherent in the set of distinctive features is the result of general perceptual principles, and that the order of appearance of phonemic contrasts corresponds to the order of complication of any complex perception. He thus contends that the laws of irreversible solidarity are weak linguistic universals. As in the case of semantics and syntax, however, there are not yet empirical grounds to support such a conclusion, as usual, the question has not been investigated.

Jakobson and Halle (1956) give the following series, presumably universal, for the successive differentiation of distinctive features. The numbers are analogous to paragraph headings or indentations. Thus 1.0 is

Consonants	dental vs labial (e.g., /t/ vs /p/)	1.0
Vowels	narrow vs wide (e.g., /i/ vs /a/)	1.1
Narrow vowels	palatal vs velar (e.g., /i/ vs /u/)	1.11
Wide vowels	palatal vs velar	1.111
Narrow palatal vowels	rounded vs unrounded	1.112
Wide palatal vowels	rounded vs unrounded	1.1121
Velar vowels	rounded vs unrounded (e.g., /a/ vs /ɑ/)	1.113
Consonants	velopalatal vs labial and dental	1.12
Consonants	palatal vs velar (e.g., /s/ vs /k/)	1.121
Consonants	rounded vs unrounded or pharyngealized vs nonpharyngealized	1.122
Consonants	palatalized vs nonpalatalized	1.123

the first contrast to be developed (/t/ versus /p/), 11 is the second contrast, etc. Later contrasts occur rarely among the languages of the world, examples in English are given where possible.

Some recent work of Preston, Yeni-Komshian, and Stark (1967) nicely illustrates how such contrasts arise in development. They have studied the distinctive feature of voicing. Among adults the acoustic manifestation of voicing is a particular relation in time between the onset of voicing and the release of a consonant—that is, all consonants, including voiceless consonants, have voicing. Voiced and voiceless consonants differ only in when voicing appears. To describe this situation Preston et al. speak of “voice onset time” or VOT, which is the number of milliseconds the release of a consonant appears before voicing. VOT can range from negative values (voicing before release) through zero (release and voicing at the same instant) to positive values (release before voicing).

Consonants with smaller VOTs are perceived as voiced, consonants with higher VOTs are perceived as voiceless. As with all distinctive features, the contrast is a relative one. The VOTs of /b/, /d/, and /g/ in English, for example, are between 0 and +5 msec, whereas the VOTs of /p/, /t/, and /k/ are between +50 and +70 msec. The same voiced-voiceless contrast in Lebanese Arabic takes values of VOT of approximately -70 msec for voiced consonants and +5 to +15 msec for voiceless consonants. That is to say, the VOT of *voiced* consonants in English is the same as the VOT of *voiceless* consonants in Lebanese Arabic, but in both languages voiced consonants have smaller VOTs.

Preston et al. have measured the VOTs of stop consonants uttered by children just at the beginning of linguistic development, at about 12 months. The children lived in either Lebanon or the United States. Because of their ages, the children were expected to be alike, the distinctive feature of voicing had not yet appeared. But because of the difference between Lebanese Arabic and English, development was expected to move in opposite directions. It turns out that Lebanese and American children both utter consonants limited to VOTs in the region common to the two languages—between 0 and +40 msec.

Are these sounds voiced or voiceless? They are neither. Ultimately Lebanese children develop a new group of sounds with VOTs in the negative range and thus make the original sounds voiceless. American children on the other hand develop a new group of sounds with VOTs in the +50 to +70 msec range and thus make the original sounds voiced.

These observations raise an interesting question about the linguistic distinction between marked and unmarked features. Roughly, a marked feature is derived from its unmarked mate through the addition of something—voicing, for example. Marked features are regarded as yoked deviations from the corresponding unmarked features. There are reasons internal to a linguistic analysis for maintaining such a dichotomy, and there are reasons (such as Jakobson's laws of universal solidarity) for supposing that the dichotomy appears in the same form in every language.

But what of the development of language? Ordinarily one would say that voiced phonemes are marked with respect to voiceless phonemes. This could be true of Lebanese Arabic but not of English if marking is the result of adding something. In English the additional phoneme is the voiceless member of each pair. There is a dilemma here for those who want to interpret the distinction between marked and unmarked features in a literal way. Either marking can be defined on internal linguistic grounds, in which case the concept loses contact with the notion of something being added, or marking can be defined as the result of something being added, in which case it leads to different classifications in different languages. It is impressive nonetheless that Lebanese Arabic and English are organized around a common core—a VOT of 0 to +40 msec. The combination of universality and idiosyncrasy in this case is quite diabolical.

Lateralization. Among all animals man is the only one with bilateral asymmetry, only man has a systematic preference for one hand over another. Since man is also alone in possessing language, we get a sense of penetrating close to the heart of things when we discover that language, like handedness, is asymmetrically organized in the brain. It has been known for more than a hundred years that the left side of the brain serves a special

function in language. Lesions to the left side of the brain produce more damaging aphasia than do lesions to the right side, and they take longer to recover from, if indeed there is any recovery at all.

The emergence of lateralization therefore seems a promising place to look for the physiological underpinnings of language acquisition. Lenneberg (1967) relates it to the existence of a critical period in linguistic development. The ability to recover from damage to the left side of the brain declines with age. A newborn with a damaged left hemisphere develops language normally with the right hemisphere, a 2- or 3-year-old loses language in some degree after damage to the left hemisphere but then quickly recovers with the right, beyond puberty recovery is always limited or nonexistent. The degree of recovery is thus correlated with the degree of lateralization before injury.

Aside from such observations of aphasia in children the development of the lateralization of speech functions has not been studied. It is possible nevertheless to state some consequences of lateralization in normal adults, and so to describe the terminus toward which development points. A series of studies at the Haskins Laboratories (Shankweiler and Studdert-Kennedy, 1966, 1967, Liberman, Cooper, Shankweiler, and Studdert-Kennedy, 1967, Shankweiler, 1968) has revealed a number of surprising effects on the perception of speech of left-hemisphere dominance. Their methodology, first employed by Kimura (1961), is suitable for young children, so developmental studies could easily be carried out along the same lines.

Kimura observed that when an adult hears two digits simultaneously in the two ears—a different digit in each—the right ear is more accurately reported. The left hemisphere therefore dominates the right. The Haskins experiments have used this dichotic task to measure separately hemispheric dominance in listening to consonants and vowels. If one ear receives /pap/ and the other /tap/, the experiment measures sensitivity to consonants, if one ear receives /pap/ and the other /pip/, the experiment measures sensitivity to vowels. In a number of studies, the right ear (left hemisphere) has been shown to be dominant in the perception of consonants, but neither ear (hemisphere) has been

shown to be dominant in the perception of vowels. This difference between consonants and vowels is reminiscent of the difference Kimura (1964) found between digits and melodies: digits were best perceived by the right ear (left hemisphere), but melodies were best perceived by the left ear (right hemisphere). One consequence of lateralization therefore seems to be a migration of consonants but not vowels to the left side of the brain. The part of the brain involved in the perception of the melodic aspects of speech, the vowels, is different from the part involved in the perception of the nonmelodic aspects, the consonants.

Vowels and consonants have been shown to differ in another respect. If small differences in speech sounds are to be discriminated, the discrimination of consonants is "categorical" but the discrimination of vowels is continuous (see Liberman et al., 1967, for a summary of the work on which this conclusion is based, see Lane, 1965, for a critical review). "Categorical" perception means that differences among speech sounds can be detected no more accurately than the sounds can be identified. It is possible to prepare a set of artificial consonants (with the aid of a device called the "pattern playback") that differ from one another by a series of small steps. Each such step is of the same physical magnitude as every other, and the series as a whole ranges from a clear instance of one phoneme (say /g/) to a clear instance of another (say /b/) with a phoneme boundary somewhere in the middle. If the sounds are consonants, successive steps within a single phoneme are poorly discriminated, whereas sounds separated by the same physical distance but belonging to different phonemes are well discriminated. In contrast, if the sounds are vowels, discrimination depends on physical separation alone, not on category membership. One is tempted to relate the findings on categorical perception to the findings on lateral dominance by saying that categorical perception occurs only in the left side of the brain.

In some degree this may be so, but matters are complicated by yet another set of observations. Certain kinds of epilepsy are treated by a complete surgical severance of the two cerebral hemispheres. In effect, the operation leaves a patient with two indepen-

dent functioning brains within a single skull. In most circumstances the left hemisphere dominates the right, but with a certain amount of contrivance it is possible to force the right hemisphere to reveal itself, even in the comprehension of speech (Gazzaniga and Sperry, 1967). In one study the experimenter speaks a short phrase ("used to tell time") and then exposes to the patient's left visual field a series of written words (one of them "clock"). The phrase reaches both hemispheres, but the series of words is so presented that it reaches only the right. Gazzaniga and Sperry's patients succeeded in matching the phrases to the words—not only does the right hemisphere understand speech but it also reads!

Unfortunately, this experiment is unclear on *what* the right hemisphere understands. Although given a phrase, the correct written word could have been selected from the perception of a single spoken word ("time" in the example given). There is no evidence therefore that the right hemisphere can comprehend syntax, although one might plausibly expect it to do so in view of the fact that language acquisition is underway long before lateralization is complete. It is clear nonetheless that the right hemisphere has access to word meanings and also to the phonemic structure of language. The latter observation tempers any extreme conclusions one might want to draw from the Haskins experiments described above. Lateralization evidently has not gone so far as to segregate completely the manner of perception (categorical or continuous) in the two hemispheres.

Phonological Rules Beside the phonemic structure of a language there are rules for using this structure. *Sporn* is not a word in English, but it could be a word—perhaps the name of an acne cure. However, *kporn* could never be a word in English, even though the individual phonemes of *kporn* are within the language just as are the phonemes of *sporn*. A phonological rule of English requires initial consonant clusters all to begin with /s/ (/l/ and /r/ follow consonants other than /s/, but /l/ and /r/ are classified as liquids, not as consonants, Halle, 1964b). Other phonological rules determine the intonation patterns of sentences. In *black board* (a kind of board) main stress falls on *board*, but in *blackboard* (a writing surface) it falls on

black. One rule for relating stress to the surface structure of sentences in English requires main stress to fall on the first vowel of an N, but to fall elsewhere in constituents of other kinds (Chomsky, Halle, and Lukoff, 1956). *Blackboard* is an N and so receives main stress on *black*, *black board* is an NP and so receives main stress elsewhere, in this case, on *board*.

There are many such rules, for examples, see Chomsky, Halle, and Lukoff (1956), Halle (1964b), Chomsky and Halle (1966), Chomsky and Halle (1968). It appears from informal observation that children continue working on phonological rules for many years, but there are few actual studies of this aspect of development. The entire question is theoretically ripe but empirically untouched. Certainly, future work should push in this direction.

We can mention the handful of studies that have been conducted on phonological questions. Berko's (1958) well-known work on children's morphology belongs in part in this category. Anisfeld and Tucker (in press) and Anisfeld, Barlow, and Frail (1967) have found evidence for sensitivity to the featural properties of sounds among 6-year-old children. However, Menyuk (1967) finds that 4- and 5-year-old American children are no better at memorizing sound sequences drawn from English than they are at memorizing sequences drawn from other languages, although they are better at repeating English sequences. And Messer (1967) finds children even younger than 4 able to discriminate between English and non-English sequences that differ by no more than one or two distinctive features. Clearly work in this area has barely begun.

LINGUISTIC APPENDIX

Take a sentence of a dozen words, and take twelve men and tell to each one word. Then stand the men in a row or jam them in a bunch, and let each think of his word as intently as he will, nowhere will there be a consciousness of the whole sentence (James, 1893, p. 199).

Thus did William James state one psychological problem. Consciousness of a whole sentence takes place in a single mind. It is

something *done* with the separate words of a sentence, and this something could not be done under the conditions of James' proposed experiment. In this section, we review what is known of the structure underlying the consciousness of sentences.

Propelled by the same revolution of thought that led to behaviorism in psychology, American linguists of the 1920s and 1930s were concerned to describe language in absolutely neutral terms. Descriptions were to reflect data. Linguistics was engaged in the discovery of the structure inherent in samples of speech. The aim was for completely objective, automatic, and rigorous procedures that would, when correctly applied, yield a correct portrayal of these structures. This would be the grammatical analysis, and it was not only to be correct, but also independent of extralinguistic suppositions. Thus Bloomfield (1933) wrote "We have learned that we can pursue the study of language without reference to any psychological doctrine, and that to do so safeguards our results and makes them more significant to workers in related fields." Although one can question Bloomfield's actual independence from behaviorism, the general tenor of linguistic thought in the 1930s was that linguistics had no concern with psychology. By the same token, psychology had little direct concern with linguistics. It is not surprising therefore that James' problem received little attention.

However, a different approach is possible, and, of late, has been under active development. In this alternative approach, linguistics aims to describe exactly what Bloomfield wanted to avoid—the specialized form of human knowledge brought to bear in the comprehension and production of sentences. Descriptions of knowledge have obvious import for psychology: whatever we know, we know by some psychological process. Thus, under its new development, linguistics makes strong psychological assumptions, with the result that it occupies common ground with psychology. As we shall see, the direction of traffic through this common region has been almost entirely one way. Discoveries in linguistics pose the challenge, psychology attempts to assimilate them. Perhaps, in the future, two-way traffic will become possible. If so, a full answer to James' problem will be at hand.

We shall then understand the process that leads to a consciousness of a whole sentence. Until that psychological millennium arrives, however, our discussion must be limited to describing the linguistic knowledge that is applied in this process, and it is to this better understood question that we now turn.

Linguists call the systematic characterizations of linguistic knowledge *grammars*. It is important to realize that these grammars are psychological theories. They strive to portray certain facts about the mind, that is, they are supposed to be psychologically correct and they stand or fall accordingly (Katz, 1964). The psychological interest in such grammars is therefore straightforward. However, it is important—even crucial—to understand the limitations placed on this claim of psychological validity. A grammar relates to mental phenomena of a particular kind, it is not an all-purpose psychological theory. In particular, it is not a theory about behavior—the actual encoding and decoding of speech. This brings us to a fundamental distinction.

Competence and Performance A sharp distinction between competence and performance has been traditional in linguistics since Saussure's *Cours de linguistique générale* (1916) and was first drawn at least as early as the eighteenth century (Chomsky, 1966). One can think about language in either of two ways. There are, first of all, actual acts of speaking and hearing, taking place in time, subject to various distractions, limited by memory and by the general weakness of human flesh. These were called *actes de parole* by Saussure and *performance* by Chomsky (1957). Performance is linguistic behavior, either encoding or decoding speech. A theory of performance would clearly be a psychological theory, a fact that presumably needs no defense. At the present time, there are no theories of linguistic performance. Indeed, there is only the most fragmentary knowledge of the relevant parameters of such a theory, although the problem is one that now inspires considerable interest. A number of recent experimental studies can be regarded as bearing on it (e.g., Miller, 1962, Miller and Isard, 1963, 1964, Mehler, 1963, Slobin, 1966, McMahon, 1963, Gough, 1965, Savin and Peichonock, 1965).

The second aspect of language is the knowledge of syntax, meaning, and sound

that makes performance possible. Saussure called such knowledge *langue*, and Chomsky has called it *competence*. A theory of competence is also a psychological theory, although of a type not usually developed by contemporary psychologists. Piaget, perhaps, comes closest in his aim to characterize the structure of logical thought. Because a grammar is concerned with knowledge, not behavior, factors (such as memory limitations, time restrictions) that are important to performance can be disregarded in thinking about competence. Competence is an idealization, an abstraction away from performance (Chomsky, 1965). Theories of performance and competence therefore deal with different aspects of language. A grammar is not a recipe for producing sentences. That recipe is given by a theory of performance. Indeed, the problem for a theory of performance is to explain just how the information represented by a grammar is realized in actual acts of speaking and hearing (Miller, 1962). The linguist's solution will not answer the psychologist's problem.

Perhaps the distinction between competence and performance, and the way they are related, will become clearer if we consider an artificial example. In Table 9 are several strings of letters.⁴ In each string there is an *a* or a *b* or both. Some of the strings have been circled. These we shall call "sentences," by which is meant that they have a certain structure in common not shared by the other strings, the "nonsentences." Table 9 is a skeletonized version of the set of all possible strings—all possible combinations of the letters *a* and *b*—and thus is analogous to the output of that hypothetical group of 1,000,000 monkeys set before 1,000,000 dictionaries, who work out the plays of Shakespeare and next week's shopping list, along with every other combination of English words, merely by pointing at random.

Our problem is to discover the structure that makes a string a "sentence" in Table 9. This can be done by the reader if he carefully examines the "sentences" and "nonsentences" listed in the table—the problem is not a difficult one. The reader can then test his discovery by judging the status of new

Table 9 "Sentences" and "Nonsentences" from a Language Consisting of the Letters *a* and *b* (many strings have been omitted). Circled Strings are "Sentences"

Length 1	<u>a</u> <u>b</u>
Length 2	<u>aa</u> <u>ab</u> <u>bb</u>
Length 3	aaa aba bbb aaaa
Length 4	abaa <u>aabb</u> baba bbbb
Length 5	aaaaa abbba bbbab
Length 6	bbbbb aaaaaa aabbba <u>aaabbb</u> bbbbbb

⁴ The example is based on a lecture by G. A. Miller in 1964.

examples Try, for instance, *aaaaabbbb*, *aaaaabbbb*, *aaaab*, *bbbbaaaa*, *aaabbb* The second and the last of these are "sentences," the rest are not

Knowledge of the principle that determines which strings are "sentences" and which are not is *competence* It is not performance Understanding the principle does not automatically lead to a correct judgment It would not, for example, in the case of a string that contained 10,000 *as* followed by 10,001 *bs* One must *count* the *as* and *bs* and judge the result against the principle Conversely, counting without knowledge of the principle will not tell one that *ab* is a "sentence" Counting is performance, whereas knowledge of the principle that adjudicates the result of counting is competence A grammar is concerned with the latter only Some further theory is needed to explain how the principle is applied to the result of counting, and this would be a theory of performance There is, of course, competence in the counting, but that is a different domain (Klima, 1966)

The status of a grammar is the same as for any other scientific theory It is an empirical hypothesis that deals with a mental phenomenon Because it is an empirical hypothesis, a grammar is either true or false, and observations are made to discover its adequacy in this respect Because it is a hypothesis about a mental phenomenon, the relevant observations have to do with knowledge of language The possibility of describing a branch of human knowledge in an explicit way is surely one of the most exciting aspects of contemporary linguistics

Let us now continue the example of Table 9 and consider several hypotheses that might account for the reader's understanding of the structures represented there

Finite-State Grammars One method of representing structure and hence competence is to construct a *state diagram* Such a diagram can be thought of as portraying a machine that can be in any of several states The machine is so restricted that when it is in one state, it can move to other states only over specified legal routes The resulting network of states and transitions will then embody a structure Can such a machine, however construed, talk correctly? In particular, can it produce the "sentences" in Table 9? To make the machine talk at all, we must

provide it with a means of recording its progress as it moves from state to state We can do this by having the machine utter the name of the state it has just left Since, in Table 9, the machine must produce strings of *as* and *bs*, all the states will be labeled *a* or *b*, and nothing else

There is one further requirement to place on our machine We want it to be superior to a mere list One could, if patient enough, prepare a list of all the "sentences" made up from *a* and *b*—writing down *ab*, *aabb*, *aaabbb*, etc The difficulty with this list is that it would be endless, because there is no longest sequence of *as* and *bs* Thus, to be an advance over a list, our machine must be finite, although it may be large It must have a finite number of states connected by a finite number of transitions, and yet be capable of producing an infinite number of correct sequences of *a* and *b* Such a machine, if successful, would provide the *grammar* of the "sentences" in Table 9 Let us now try to construct a grammar along these lines

Figure 10a shows a machine of three states and three transitions, which is able to produce the "sentence" *ab* It cannot, however, produce

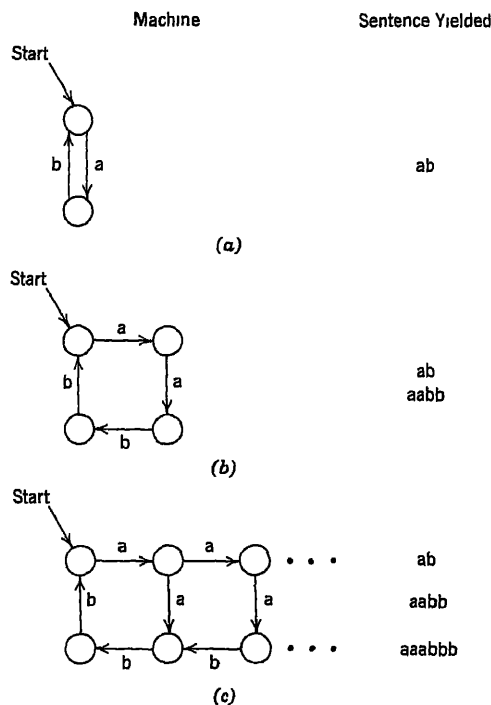

Fig 10 Finite-state machines

"sentences" longer than this. Running the machine twice yields a repetition, not a new "sentence," since we obtain *abab*. In order to produce the next longer "sentence" we must add two new states and three new transitions, as in Fig 10b. This new machine produces *aabb* as well as *ab*. However, it produces nothing else, and to enrich it we must add two more states and three more transitions, as in Fig 10c. However, this machine is likewise restricted—its longest "sentence" is *aaabbb*. In short, for each additional length of sentence, we must add further states and transitions. Since the list of "sentences" consistent with Table 9 is endless, the addition of states and transitions is endless also. The machine thus fails the last requirement stated above. It is not superior to a mere list, which means that different kinds of grammars are needed.

Before considering these different grammars, however, it should be noted that the "sentences" in Table 9 and the grammars in Fig 10 are not simply formal exercises. On the contrary, they are directly relevant to the concerns of this chapter. English has sentences of the kind listed in Table 9, and much psychological theorizing accounts for structures of the kind diagrammed in Fig 10. The fact that Fig 10 cannot represent the "sentences" in Table 9 therefore means that much psychological theorizing cannot account for significant portions of the structure of English. Let us take up the matter of structure first.

The "sentences" in Table 9 are built like an onion. The shortest is *ab*. The next longer consists of second *ab* sealed inside the first *ab* giving *aabb*. The next longer yet results from inserting still another *ab* into *aabb*, giving *aaabbb* and so on. If we use parentheses to indicate how the *as* and *bs* are paired, the "sentence" of length six would be written *(a(a(ab)b)b)*. Such structures are called embeddings, and, if not too long, are commonplace in English. (*The race (that the car (that the people sold) won) was held last summer*) stretches the bounds of credulity but it is a perfectly grammatical sentence (Miller, 1962).

Now let us take up psychological theory. The way to construct a finite-state device, clearly, is to link states by transitions. If the device is also a model of a learner, then it

must be exposed to each link in the chain so that states will be connected by transitions moving in the correct directions. In the case of Fig 10a, the device must have been exposed first to an *a* and then to a *b*. This requirement is inescapable. As long as the structure to be acquired can be presented in this steplike way, a finite-state device will faithfully reproduce it. Other structures, however, lie beyond its grasp.

This limitation—faithful reproduction of transitions but nothing else—is shared by every stimulus-response theory of learning, from the simple (Skinner's) to the complex (Osgood's). It is inherent in the basic S-R paradigm. Learning occurs when one presents an appropriate stimulus together with the correct response and stamps in a connection between the two through (depending on the theory) reinforcement, repetition, drive reduction, etc. All S-R theories are variations on this basic empiricist theme, and they all lead to the development of a finite-state device. This is the relevance of Table 9. The principles underlying the "sentences" there could not be learned through *any* process consistent with an S-R theory. The reader who understands the structure of these "sentences" is himself a refutation of all consistent S-R models.

This critique might be answered by observing that there is no proof that our knowledge of the "sentences" in Table 9 is anything other than what the diagrams in Fig 10 claim. The requirement of infinite productivity might be psychologically meaningless, and perhaps an S-R analysis expresses the processes that actually take place.

There are, however, at least three things wrong with this defense. One is simply that it fails to explain how S-R theories are logically superior to the compilation of lists in the case of embedded materials, that is, how S-R theories are actually theories.

A second difficulty is that the diagram in Fig 10 cannot account for correct judgments about "sentences" never before encountered. If a novel "sentence" goes beyond the current degree of complication of a finite-state device, then it must be rejected as a "nonsentence," unless there is further training. This is the point of the test the reader was asked to take. If the reader had discovered the principle underlying the "sentences" in Table 9, he

could correctly judge the sentencehood of novel strings without additional instruction. And if the reader could do this, then what he had learned could not be represented by a finite-state device.

The third difficulty is the opposite side of the coin. If we assume that a speaker's knowledge of English *can* be represented by a finite-state device, then we are forced to hold quite incredible beliefs about the learning ability of children. Take the following sentence: *The people who called and wanted to rent your house when you go away next year are from California* (Miller and Chomsky, 1963). It contains a grammatical connection between the second word (*people*) and the seventeenth word (*are*) changing either but not both of these words to the singular form would produce an ungrammatical sentence. If the connection between *people* and *are* is carried by a finite-state device, then each of us must have learned a unique set of transitions spanning 15 grammatical categories. Making the conservative estimate that an average of four grammatical categories might occur at any point in the development of an English sentence, detecting the connection between *people* and *are* signifies that we have learned at least $4^{15} = 10^9$ different transitions. This is, however, a *reductio ad absurdum*. As Miller and Chomsky point out, "We cannot seriously propose that a child learns the values of 10^9 parameters in a childhood lasting only 10^8 seconds" (1963, p. 430). And even a highly efficient child, one who somehow *could* learn 10 transitions a second, would still miss the dependency when *people* and *are* are separated by 16 words or more.

These three difficulties add up to a single flaw. There is no way for a finite-state device to express the idea of embedding—the insertion of one component inside another component like itself. However, embedding is a psychological fact. It is what the reader grasped in Table 9. It is behind the comprehension of sentences such as *the race that the car that the people sold won was held last summer*, as well as *the people who called and wanted to rent your house when you go away next year are from California*. What is needed therefore is a hypothesis about this mental ability. One is introduced in the next section.

Recursiveness and Linguistic Abstraction. Finite-state devices in general and S-R models in particular can copy only those structures that consist of states and transitions among them. These models will misrepresent anything that possesses some other structure. That was the difficulty with the description of the "sentences" in Table 9 by means of the state diagrams in Fig. 10. If the reader understands the principle underlying these "sentences," he can tell that the part missing from *aab* is a second *b* to go with the first *a*. Similarly, he can tell that the sentence *the car that the people sold was held last summer* is peculiar because there is an incorrect verb for the noun-phrase, *the car*. In both cases, part of what is known about the structure of the sentence is that elements separated from each other actually belong together and not with the material that separates them. What they jointly belong to is an important fact about the sentence, and a correct linguistic representation must somehow portray it. It is on this hidden structural feature that a finite-state device founders.

Consider now the following two grammatical rules. Together, they will produce all and only the "sentences" consistent with Table 9.

$$X \rightarrow aXb$$

$$X \rightarrow ab$$

The arrow (\rightarrow) means that the element on the left is rewritten as, or becomes, the elements on the right. By employing a further notational convention—that parentheses in a rule indicate optionality—the possibility of choosing or not choosing an element—the two rules above can be collapsed into one, as follows:

$$X \rightarrow a(X)b$$

One may apply the expanded version of this rule (with the *X*) indefinitely. Each application lays down an *a* and a *b* with another *X* in between. The new *X* calls for application of the rule again, *ad infinitum*. This is embedding. The development of a "sentence" comes to an end when the option of not including *X* is taken. Figure 11 shows the successive steps taken in producing a "sentence" of length six, *aaabbb*.

The constituent in these "sentences" labeled *X* is the part to which each *ab* pair belongs, even though they are separated by other *ab* pairs. The existence of *X* is essential

Fig 11 Generation of aaabbb by phrase-structural rules

to the recursiveness of the rule, since its presence on the right is the only feature that requires another application of the rule

However, note one important thing. The constituent X is *abstract*. It never appears in the final form of a sentence, only in its derivation. aXb is not a "sentence" in Table 9, just as the equivalent in English, *the people*. Sentence *are from California*, is not a sentence. Nonetheless, an abstract constituent is part of the structure of these sentences. It is such an abstraction that the reader gleaned from Table 9 and it is such an abstraction that he discovers in the sentence, *the people who called and wanted to rent your house when you go away next year are from California*. According to this hypothesis, speakers can grasp aspects of sentence structure that are never included in the overt form of a sentence. The question of linguistic abstractions poses a most challenging problem for psychologists. Somehow, linguistic abstractions are developed by children—for just as the reader learned about an invisible X in Table 9, children learn about structural features in English that are never presented to them.

Phrase-Structure Rules A grammar, we have said, represents linguistic knowledge. A grammatical rule, accordingly, represents a bit of linguistic knowledge. In the case of a rewriting rule such as $X \rightarrow a(X)b$, the knowledge represented is that $a(X)b$ is a species of the genus X . The rule itself is simply a means of expressing this idea.

Many aspects of language take such a form. *The frog caught a mosquito*, for example, is a sentence, *the frog* and *the mosquito* both are noun phrases, and *caught the mosquito*, in turn, is a verb phrase. Knowledge of these elementary facts can be represented naturally by means of rewriting rules.

Table 10 shows how it is done for *the frog caught the mosquito*. Note that each of the examples given above, where one constituent is an instance of something else, is represented in the table by a separate rule. The derivation makes the genus-species relation, as it applies to the sentence, explicit.

It is easy to show that the relations established by the rules in Table 10 correspond to facts that speakers of English know about *the frog caught the mosquito*. First, if a speaker is asked to divide the sentence into two major parts, the split will most likely be made between *the frog* and *caught the mosquito*, that is, between the NP and PredP of the first rule. If he is now asked to divide *caught the mosquito* into two parts, the line will come between *caught* and *the mosquito*, that is, between the V and NP of the second rule. It is very unlikely that a speaker would divide *the frog caught the mosquito* into *the* and *frog caught the mosquito*, or divide *caught the mosquito* into *caught the* and *mosquito*. Speakers honor the rules because the rules reflect information speakers have about the sentence. This correspondence can be revealed in a second way.

Table 10 Rewriting Rules for Producing a Simple Declarative Sentence

- 1 $S \rightarrow NP \text{ PredP}$
- 2 $\text{PredP} \rightarrow V (NP)$
- 3 $NP \rightarrow \text{Art } N$

S = sentence NP = noun phrase PredP = predicate phrase Art = article N = noun V = verb. Rule 2 covers both transitive and intransitive verbs, and for this reason has NP as an optional development. (See Chomsky, 1965, for a more detailed treatment.)

Suppose that we take *the frog caught the mosquito* and try to derive from it another sentence in the following manner (Miller, 1962) We try to find a single word that can replace a *group* of words in the original sentence, without changing the grammatical structure Our interest lies in seeing which groups of words can be replaced Replacements exist only for the constituents of the sentence—English has no words that belong to no constituents A series of these derivations is shown in Table 11, and it can be seen that the replacements obtained in this manner correspond exactly to the derivation obtained through application of the rules in Table 10 We have here hard-core evidence for the validity of the rules in Table 10

The structures portrayed in Tables 10 and 11 are a part of the phrase structure of English Accordingly, the rules in Table 10 that produce this structure are called *phrase-structure rules*, and the diagram in the table is called a *phrase marker* The function of the rules is to define which constituents of sentences are superordinate to which other constituents, to establish the order of constituents, to display the grammatical elements of the sentence (e.g., NP), and to define the so-called basic grammatical relations—subject of a sentence, object of a verb, etc (See the section on “Predication and the Basic Grammatical Relations” above) The phrase marker is the structure produced through application of the rules It can be presented as a diagram, as in Table 10, or by means of labeled brackets

(((the) (frog)) ((caught) ((the) (mosquito))))
S NP Art N VP V NP Art N

includes exactly the same information as Table 10, and both represent the structure that speakers of English find in *the frog caught the mosquito*

Note that grammatical rules *represent* linguistic structure They describe tacit knowledge, not explicit knowledge No one claims that the rules given in Table 10 are known to speakers of English as rules If that were actually the case, linguistics could not exist as a science—the field would be as pointless as would a “science” setting out to discover the rules of baseball The distinction is perhaps obvious, but its importance justifies some elaboration

One can imagine a series of interpretations

Table 11 The Result of Replacing Groups of Words by Single Words in a Simple Declarative Sentence

A Sentence				
It		acted		
The	frog	acted		
The	frog	caught		it
The	frog	caught	the	mosquito

Based on Miller, 1962

of the rules in Table 10 At the weak end of the series, phrase-structure rules might be regarded as summarizing regularities in behavior In this case, $S \rightarrow NP \text{ PredP}$ means that when English sentences occur, they consist of noun phrases followed by predicate phrases There is no interest at this end of the series in representing linguistic competence The relevant observations are the frequency of sentences following the NP PredP format, of PredPs following the V NP format, and so forth There is no doubt that such observations would falsify the weak interpretation of Table 10 As a count of the sentences appearing in this chapter would reveal, sentences like *the frog caught the mosquito* simply are not common

At the opposite extreme, the strong end of the series, the claim is that English speakers know the rules in Table 10 in much the form that the rules take when written Clearly, this claim is false for the vast majority of English speakers

The midpoint in this series of interpretations is the one intended for Table 10 English speakers do not know the rules in Table 10 But what they do know (it is claimed) is represented by these rules Observations relevant to the intermediate interpretation have to do with a speaker's intuitions—for instance, that *the mosquito* is a grammatical constituent in English, whereas *caught the* is not As we have already seen, such observations support this intermediate claim

Phrase-structure rules, interpreted in the intermediate sense, are said to *generate* sentence structures A term like “generate” tempts us to think that speakers actually plan sentences along the lines outlined in Table 10—they first decide to utter a sentence, then decide that the sentence will consist of an NP and a PredP, and then, only at the end, decide what vocabulary to use Such a scheme is one possible, though improbable hypothesis

about linguistic performance (Yngve, 1960, 1961, Johnson, 1968) However, this hypothesis is not part of the grammatical analysis in Table 10 A grammar is neutral with respect to hypotheses about performance The term *generate* is used by grammarians in a logical rather than a mechanical sense As the linguist Lees once put it, a correct grammar generates all the possible sentences of a language in the same way that a correct zoology generates all possible animals Both capture the structural relations within their subject matter The term *generate* is used throughout this chapter in its logical, nonmechanical sense

The linguistic observations made so far serve a fairly obvious purpose The parsing of *the frog caught the mosquito* given in Table 10 does not require elaborate defense The facts are straightforward, and the principal merit in discussing them at all is that they acquaint the reader with some linguistic notation at a point where it is reasonably easy to see what the notation means However, there are more profound, and psychologically more significant, insights entailed by three other linguistic concepts, and it is to these concepts that we now turn

Transformations and the Notions of Deep and Surface Structure In a general way, language can be described as a system whereby sound and meaning are related to each other That sound and meaning are separate, and so need relating, is evident from paraphrase, where the same meaning is expressed in different patterns of sound (*the man pursued the woman* and *the woman was pursued by the man*), and from ambiguity, where the same pattern of sound has different meanings (*outgoing tuna*) Between sound and meaning stands *syntax* The relation between sound and meaning is therefore understood to the degree that the syntax of a language is under-

stood In this section we examine what is known of this relation

Rationalist philosophers have argued since the eighteenth century that sentences have both an inner and an outer aspect—the first connected with thought and the second with sound (Chomsky, 1966) The kind of evidence that leads to this conclusion, and hence to the phenomenon of concern here, is given in Table 12 (after Miller and McNeill, 1968) The three sentences on the left of Table 12 all have the same superficial form They start with a pronoun, *they*, followed by *are*, followed by a progressive form, followed by a plural noun Despite superficial identity, however, there are clear differences in structure among these three sentences To understand the differences, we will eventually need the notions of a transformation rule and of deep and surface structure

Sentence (a) differs from sentences (b) and (c) in several fairly obvious respects One difference is that the two kinds of sentence accept pauses in different places With sentence (a), one might say *they—are buying—glasses*, but probably not *they—are—buying glasses* It is the opposite with sentences (b) and (c) One could say *they—are—drinking companions* or *they—are—drinking glasses*, but not *they—are drinking—companions* or *they—are drinking—glasses*, unless the reference was to cannibalism or suicide A second difference is in the proper location of articles We have *they are buying the glasses* but not *they are the buying glasses* We have *they are the drinking companions* but not *they are drinking the companions*

The location of pauses in a sentence is fixed by its phrase structure Pauses tend to go around constituents, not inside them The location of articles is similarly determined by phrase structure They go before NPs only We can thus summarize the differences be-

Table 12

Sentences	Paraphrases	Nonparaphrases
a. They are buying glasses	—	—
b. They are drinking glasses	They are glasses to use for drinking	They are glasses that drink.
c. They are drinking companions	They are companions that drink.	They are companions to use for drinking

tween sentence (a) and sentences (b) and (c) by saying that they have different phrase structures. In particular, the progressive form in sentence (a) is associated with the verb *are*, whereas in sentences (b) and (c), it has moved over to the plural noun. The essential parts of the three phrase markers are as follows: (*they*) (*are buying*) (*glasses*), (*they*) (*are*) (*drinking companions*).

Sentence (a) and sentences (b) and (c) are distinguished in their *surface structure*. The difference, as we have seen, has to do with the distribution of pauses and the location of articles. Surface structure is also intimately connected with stress and intonation. In general, the surface structure of a sentence has to do with phonology—with one of the two aspects of language that need to be related by syntax.

Let us now look more carefully at sentences (b) and (c). They accept pauses in the same way, they take articles at the same places, they are accordingly bracketed in the same way, and, indeed, they have the same surface structure. But it is clear that they are not structurally identical throughout. They differ in a way that is important to meaning, the other aspect of language that is to be related by syntax. That they differ in meaning can be seen in the paraphrases and nonparaphrases of the two sentences in Table 12. Sentence (b) means "they are glasses to use for drinking," and sentence (c) means "they are companions that drink." Exchanging the form of the paraphrase between (b) and (c) leads to a nonparaphrase. Sentence (b) does not mean "they are glasses that drink" any more than sentence (c) means "they are companions to use for drinking." Despite the identity of surface form, (b) and (c) differ importantly in underlying form. We shall say that they differ in *deep structure*, saving until later a more precise definition of what this means. First, however, let us note two implications that follow from the fact that (b) and (c) have the same surface structure but different deep structures.

One is that the *relation* between deep and surface structure must be different in the two sentences. The statement of this relation is assigned a special place in a grammar. It is done by *rules of transformation*, and it is these rules, together with the deep and surface structure of sentences, that embody the

connection between sound and meaning in a language. The reader will have realized, of course, that in a statistical sense, sentences (b) and (c) are freakish. The vast majority of sentences that have different deep structures and different transformations also have different surface structures. Sentences (b) and (c) happen not to, but for this very reason they conveniently illustrate what is true of all sentences. Every sentence, however simple, has some kind of deep structure related to some kind of surface structure by means of certain transformations. The substance of grammar consists of making explicit these three terms.

The second implication of the difference in paraphrase between sentences (b) and (c) is that the deep and surface structures of sentences are not identical. This is evidently true of at least one of these sentences, (b) or (c). In fact, it is true of all sentences. Transformations provide enormous flexibility in developing surface structures from deep structures, and this advantage has been pressed by language in even the most elementary sentence types (an example with simple declaratives is given below). Thus the deep structure of every sentence is abstract in the sense given above. The underlying structure, the part connected with meaning, is not present in the overt form of any sentence. The existence of linguistic abstractions is a universal phenomenon—acquisition of them is a basic fact about the development of language and on its success rests the emergence of all adult grammar. It would be impossible to understand sentences (b) and (c) correctly if this were not so.

All these concepts—deep structure, surface structure, linguistic abstraction, and the way transformations tie them together—can best be seen in an example. The one we shall use is borrowed from Miller and McNeill (1968) and is based on Chomsky (1957). Consider the following sentences:

<i>He walks</i>	(present singular)
<i>They walk</i>	(present plural)
<i>He walked</i>	(past singular)
<i>They walked</i>	(past plural)

These four sentences mark two distinctions: number (singular and plural) and tense (present and past). Number is marked both in the form of the pronoun and in the in-

flexion of the present-tense verb Tense is marked in the inflection of the verb Let us focus on the verbs, for it is here that a transformation becomes involved

There are three verb suffixes $-s$, $-\phi$ (which means null, but is a suffix all the same), and $-ed$ They encode information of a certain type, namely, the form of the verbal auxiliary, so we might suppose that this information can be expressed by a re-writing rule of the type already discussed If we label the genus part of the rule C, then we can use the following context-sensitive rule

$$C \rightarrow \left\{ \begin{array}{l} -s \text{ in the context } NP_{\text{sing}} \\ -\phi \text{ in the context } NP_{\text{pl}} \\ -ed \end{array} \right\}$$

and summarize all four of the sentences above by a single schema NP + V-C

Let us now complicate the sentences slightly by incorporating an auxiliary verb, *be*, and see what happens to C

He is walking
They are walking
He was walking
They were walking

The first thing to note is that using a form of *be* adds $-ing$ to the following main verb C, for its part, has moved forward It is no longer attached to the main verb but to the auxiliary, and we have *be-s* (pronounced *is*), *be-φ* (pronounced *are*), and *be-ed* (pronounced *was* or *were*, number being marked on past-tense verbs in this case—a detail we can ignore) The schema for these sentences therefore is, NP + *be*-C + V-*ing*

Next, consider the effect of adding a different auxiliary verb, a form of *have*, to the original sentences In doing so, we obtain

He has walked
They have walked
He had walked
They had walked

The main verb again takes a suffix, this time, $-ed$, and C again moves forward to the auxiliary It is the same therefore as when *be* is the auxiliary, except that different pronunciation rules are involved (*have-s* is *has*, *have-φ*

is *have*, *have-ed* is *had*) and the main-verb suffix is $-ed$, instead of $-ing$ By indicating these changes, we obtain the schema NP + *have*-C + V-*ed*, for the use of *have* as an auxiliary

The two auxiliaries can be combined, of course, as in these sentences

He has been walking
They have been walking
He had been walking
They had been walking

Both auxiliaries have the effects already demonstrated *Be* adds the suffix $-ing$ to the following verb and *have* adds a "past" suffix to *be* (In this case, it is *be-en*, another difference in detail that we can ignore) C also follows its pattern, for it is still attached to the first auxiliary verb The schema therefore is NP + *have*-C + *be-en* + V-*ing*

These sentences can be complicated still further by adding one of the modal auxiliaries Modals are the words *will*, *can*, *may*, *shall*, *must* Let us add *will*

He will have been walking
They will have been walking
He would have been walking
They would have been walking

C has moved forward again, attached now to the modal *Have* still adds a "past" inflection to the following *be*, and *be* still adds $-ing$ to the following main verb The schema thus is NP + M-C + *have* + *be-en* + V-*ing*, where M stands for "modal"

It is evident from these examples that C always appears with the first member of an auxiliary construction, no matter how long this construction is The location of C is a fact known to all speakers of English—*he will had been walking* obviously is not the way to indicate past tense in an auxiliary construction Part of an English speaker's competence thus has C at the start of a verb phrase Another part involves the contingency between *have* as an auxiliary and a following "past" inflection, as well as the contingency between *be* as an auxiliary and the following $-ing$ Let us try to represent these facts about competence by constructing a rule that meets the following two conditions (1) the true order of elements is maintained, and (2) elements contingent on one another are placed together This will lead to a simple solution

Meeting the first condition requires placing C first, then M, then *have*, and finally *be*. Since C appears in every sentence, our rule must make it obligatory. The remaining constituents, however, are optional, so we write them with parentheses. Let us call the whole construction "auxiliary," abbreviate it "Aux," and put down the following rule:

Aux \rightarrow C (M) (*have*) (*be*)

The following main verb V is omitted from this rule because it is introduced along with Aux by the PredP rule, which is now enlarged to read

PredP \rightarrow Aux V (NP)

The Aux rule is still incomplete, since it does not yet meet the second condition. The contingencies to be represented are that *have* goes with *-en* (or *-ed*), and *be* goes with *-ing*, so we write these elements together, and thereby produce the following

Aux \rightarrow C (M) (*have-en*) (*be-ing*)

after which there will always be a V

We now have all but one of the rules necessary to generate the examples previously given. The missing one, a transformation, will be provided shortly. However, in order to see the need for the transformation, and to appreciate the role it plays in representing the structure of these sentences, we should first see the result of producing sentences without it. The structural relations to be expressed by the transformation will be those not expressed by the rules already developed. If we have done our job well, the division between the two kinds of rules, the transformation and the phrase-structure rules, will correspond to a real division between two kinds of structural information within sentences.

Figure 12 contains a phrase marker generated by the phrase-structure rules presented in the preceding paragraphs. Note that the order of elements at the bottom of the phrase marker is *they* + *Past* + *will* + *have* + *en* + *be* + *ing* + *walk*. This string and its associated structure is the deep structure of *they would have been walking*. The surface structure is a specific instance of the last schema given above—*they* + *will-Past* + *have* + *be-en* + *walk-ing*. The deep structure thus differs from the surface structure in the order of affixes and verbs. Accordingly, it is abstract in the sense used here, since the

Fig. 12 Deep structure of *they would have been walking*

deep-structure order never appears overtly. It is important to realize, nonetheless, that the deep structure in Fig. 12 reflects actual linguistic knowledge—the information summarized by C is always first in a predicate phrase, *have* and *-en* do always appear together, just as *be* and *-ing* do.

The deep structure therefore must be transformed to obtain the surface structure. The transformation is simple: wherever the sequence affix-verb appears in the deep structure, change the order to verb-affix (Chomsky, 1957). If the reader applies this transformation, he will find the surface structure of *they would have been walking* rolling out quite automatically.

There remains one important point. Note that the linguistic information expressed by the phrase-structure rules in generating *they would have been walking* is fundamentally different from the information expressed by the transformation rule. Which is to say that the distinction between the two is linguistically meaningful. The former rules define such matters as the genus-species relations within the sentence (e.g., *they* is an NP), establish the basic order of elements (e.g., C is first in the PredP), and indicate what the elements are (e.g., *have-en* is an element). Information of this kind is essential for obtaining the meaning of the sentence. The relations just mentioned, among others, are exactly what we understand of *they would have been walking*.

The transformation, in contrast, makes no contribution to meaning. It exists only because sound and meaning are not identical in English (or any language), and its sole purpose is to state the relation between them.

The distinction between phrase-structure and transformation rules is thus fundamental to the analysis of language. Without it, the insight that sound and meaning are separate in language would be lost, and to suggest, as some have done, that transformations are methodologically unsound because they lead to arbitrary linguistic solutions, is to miss the entire point of transformational grammar.

The distinction between sound and meaning is a basic justification of transformational grammar, but the use of transformations in grammatical analysis is supported by other arguments as well. One is economy. If we dispense with transformations and try to generate sentences with phrase-structure rules alone, the result becomes unnecessarily complex. The sentences given above, for example, require eight different and independent phrase-structure rules, one for each combination of auxiliary verb and C, instead of the single phrase-structure rule required when a transformation is allowed. Without the transformation, we would need at least the following rules: $Aux_1 \rightarrow V-C$, $Aux_2 \rightarrow be-C + V-ing$, $Aux_3 \rightarrow have-C + V-ed$, $Aux_4 \rightarrow have-C + be-en + V-ing$, $Aux_5 \rightarrow M-C + V$, $Aux_6 \rightarrow M-C + be + V-ing$, $Aux_7 \rightarrow M-C + have + V-ed$, and $Aux_8 \rightarrow M-C + have + be-en + V-ing$. Note that these rules cannot be collapsed onto one another by means of the parentheses notation used before, since there is no way to locate C correctly if optional elements are introduced. The phrase-structure version of the auxiliary therefore not only overlooks valid linguistic generalizations—such as the fact that C always appears first in the auxiliary, or that there is an auxiliary, or that *-ing* depends on *be* and not on *V*—but it is simply cumbersome. Relative economy is always an argument in support of one theoretical interpretation over another, and using it in the present case inclines the balance toward a transformational grammar.

The argument of economy has special significance in the context of language acquisition. We prefer to think of children doing the simpler thing, whatever that might be. In the case of linguistic development, the simpler thing is to acquire a transformational grammar instead of a phrase-structure grammar. Accordingly, it is the former that we suppose is learned.

The affix-transformation used in generating

the English auxiliary verb is one rule within a vast and intricate network of transformations making up the language. Passive sentences, negation, questions of various kinds, conjunctions, complements, and many others, all depend on transformations. The technical literature dealing with these rules is large and sophisticated, rather than summarizing it here, a task almost as unnecessary as it is hopeless, the interested reader is encouraged to turn to original sources. A book edited by Fodor and Katz (1964) contains a number of significant papers. In addition, one should look at Chomsky (1957, 1962, 1964, 1965, 1966), Chomsky and Miller (1963), Chomsky and Halle (1966), Fillmore (1965), Katz (1966), Katz and Postal (1964), Miller and Chomsky (1963), Postal (1964), and Bach and Harms (1968). A review of transformational grammar written for psychologists is contained in Miller and McNeill (1968).

There is one set of transformations of special significance, however, and this section will conclude with a discussion of them. Recall the artificial language presented in Table 9. Its "sentences" were built like an onion—such structures as $(a(a(ab)b)b)$. The rule given to generate the "sentences" in Table 9 was $X \rightarrow a(X)b$, in which there is an abstract recursive element, X. This much is phrase structure and it has an exact analogy in English (and all other languages).

In developing the deep structure of any sentence, it is possible to include the element S, thus calling for the insertion of *another* deep structure at that point. That sentence, in turn, may also have an S in it, calling for the insertion of yet another deep structure, and so forth. The result is the same onion-like structure presented in Table 9, and it has the same effect—making unlimited productivity possible through recursion. Figure 13 shows a succession of such deep structures, each with another deep structure embedded within it.

Figure 13 is the result of applying phrase-structure rules alone. It is, in other words, the deep structure of *(the ostrich (that was terrified by the zebra (that the hunter shot)) stuck its head in the sand)*, a sentence with two relative clauses. English employs several transformations to develop this surface structure from the deep structure in Fig. 13. In discussing them, we shall use terminology

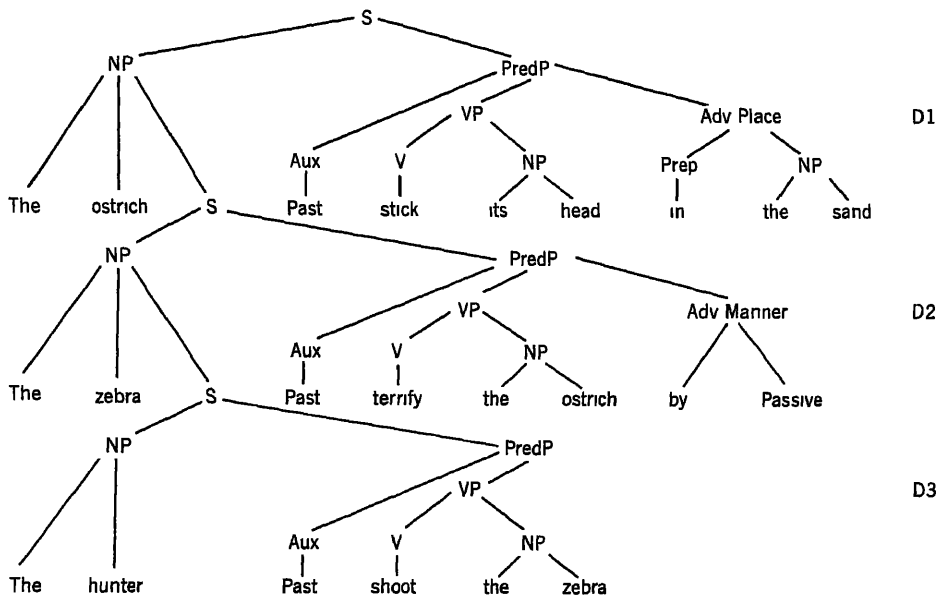

Fig 13 Deep structure of *the ostrich that was terrified by the zebra that the hunter shot stuck its head in the sand*

suggested by Lees (1960) and call the structure containing S the *matrix* and the S contained the *constituent*. Thus D3 in Fig 13 is the constituent of the matrix D2, and both are the constituent of the matrix D1. In Fig 13, D3 is only a constituent, D1 is only a matrix, but D2 is both—a matrix for D3 and a constituent (containing D3) for D1.

These three components are complete structures unto themselves. If developed in isolation (ignoring the S in D1 and D2), each would result in a sentence. D1 is the deep structure of *the ostrich stuck its head in the sand*, D2 is the deep structure of a passive sentence, *the ostrich was terrified by the zebra*, and D3 is the deep structure of *the hunter shot the zebra*. It is obvious that more is required in combining these elementary structures than simply applying the transformations that each calls for alone—the auxiliary transformation in every case, and the passive transformation in D2. Doing only this much produces non-English: *the ostrich was terrified by the zebra the hunter shot the zebra stuck its head in the sand*. To avoid a word salad like this, an embedding transformation must delete double occurrences of the same NP. Not every NP repeated in an English sentence need be deleted, of course.

The ostrich stuck its head in the sand and the ostrich ate the worm is grammatical even though redundant or ambiguous. However, in the case of an embedded relative clause, deletion must occur, and the rule is that when the same NP is both a matrix subject and a constituent object, the object-NP is moved to the front of its sentence structure and replaced by the word *that*. Let us call this operation the deletion transformation. In the case of Fig 13, it produces *the ostrich that the zebra that the hunter shot stuck its head in the sand*. Applying the auxiliary transformation to this structure wherever called for (e.g., *Past-shoot* becomes *shot*), and the passive transformation to D2, the surface structure, of which Fig 13 is the deep structure, rolls out. (Actually, such "singular" transformations are all applied first to the most deeply embedded S, then to the next most deeply embedded S, and so on up to the top, before the embedding transformations are applied. See Chomsky, 1965, for a discussion of such transformational cycles.)

Again, notice that a natural distinction exists between the information contained in the transformation and the information contained in the deep structure. As before, the

information in the deep structure has to do with meaning and that of the transformation with the relation between sound and meaning. When one understands a relative clause, he grasps the fact that there are two or more deep structures, one inserted in the other, with the deletions *not* performed. Whether one obtains the meaning of *the ostrich that was terrified by the zebra that the hunter shot stuck its head in the sand* depends on knowing that the first *that* means *ostrich* and the second *that* means *zebra*, which is to disregard both deletions in the semantic interpretation of the sentence.

There is one more point important in this brief introduction to syntax. If transformations are correctly stated in a grammar, they apply automatically whenever the proper conditions exist in the deep structure. In other words, transformations are obligatory (Chomsky, 1965; Katz and Postal, 1964). The specification of the "proper" conditions is done by the *structural index* of a transformation and setting it down is an important part of writing a transformational rule. Should the structural index be wrong, a transformation will inevitably relate wrong deep and surface structures, even though the operations described in the transformation and themselves

correct for the appropriate cases. To supplement the rules already mentioned, then, we must add that the auxiliary transformation applies to any occurrence of *affix + V*, the passive transformation to any occurrence of *NP₁, Aux, V, NP₂ by + Passive* (the subscripts indicating that the two NPs must be different and the dots indicating that other, unspecified, material can be inserted), and the relative-clause transformation to any case where the matrix-subject and the constituent-object are the same NP. The structural index is clearly part of grammatical knowledge. Applying the relative-clause transformation to two deep structures where the subject and object-NPs are different results in a sentence that expresses the wrong meaning. If, for example, the deep structures of *the ostrich stuck its head in the sand* and *the ostrich ate the worm* are connected by the relative-clause transformation, meaning shifts and the result becomes something out of Alice in Wonderland—*the ostrich stuck its head in the sand that ate the worm*. Since violation of the structural index of a transformation leads to an inappropriate expression of meaning, it is evident that the structural index is a part of the relation between meaning and sound.

16. *Development of Mental Abilities**

NANCY BAYLEY

With the 1905 publication by Binet and Simon of the first version of their tests of intelligence, a practical device became available for use in the measurement of mental abilities. These tests, and their successive revisions and adaptations by the original authors and then by others (in the United States, for example, Goddard, 1910, Kuhlmann, 1912, 1939, Terman, 1916, Terman and Merrill, 1937, 1960), inaugurated a new field in psychology and education. The mental test soon became an established tool for use in research, in diagnosis, and in theoretical formulations about intelligence.

In the 60 years since its inception, the mental (or intelligence) test has undergone many changes and refinements, and it has had a profound influence on theories of the nature of mental processes as well as on the methods of investigation into mental abilities.

The early history of mental testing has been ably reviewed a number of times, and need not be repeated here. Reference may be made, for example, to Goodenough (1949, 1954), Jones (1954), Hunt (1961), Anastasi (1961), and Tuddenham (1968).

DEFINITION

In the first 10 or 15 years of the use of tests of intelligence a controversy developed over the definition of "intelligence." Although there was much in common among the vari-

ously worded definitions, there were two principal areas of difference. (1) There was disagreement over whether intelligence is a general unitary function on the one hand or a composite of several or many more or less independent abilities on the other. (2) There was disagreement over whether intelligence is innate, and grows in a child in somewhat the same way as he grows in stature, or whether mental abilities are learned and thus increased or decreased in accord with the degree of enrichment or impoverishment of a child's environment. Although the controversy has waxed and waned, it has never been quite resolved. This failure of resolution may be only an indication of our lack of information and the need for further research in this area.

THEORIES OF INTELLIGENCE

The efforts to define intelligence reflect the wide range of interpretations of its nature and causal determinants. They range from strongly genetic orientations "an inherited capacity of the individual which is manifested through his ability to adapt and to reconstruct the factors of his environment in accordance with his group" (Boynton, 1933), or "by intelligence, the psychologist understands inborn, all-round, intellectual ability" (Burt et al., 1934), through neutral descriptions of mental processes such as Terman's "ability to carry on abstract thinking" (1925), Thorndike's ability "to make good responses from the point of view of truth or fact" (1926), and Wechsler's "the aggregate or global capacity to act purposefully, to think rationally and to deal effectively with [one's] environment" (1958), to emphasis on the role

* This research was supported in part by Grant MH08135 from the National Institute of Mental Health, United States Public Health Service. I am indebted to John R. Reid for critically revising the manuscript.

of the environment, as in Hunt's (1961) "intellectual capacities based on central processes hierarchically arranged within the intrinsic portions of the cerebrum [processes] 'approximately analogous to the strategies for information processing and action with which electronic computers are programmed [Therefore,] assumptions that intelligence is fixed and its development is predetermined by the genes are no longer tenable." An even more strongly environmental position is expressed by Hayes (1962), who concludes that "manifest intelligence is nothing more than an accumulation of learned facts and skills—innate intellectual potential consists of tendencies to engage in activities conducive to learning, rather than inherited capacities, as such." What may be the most extreme pro-environmental position has been expressed by Liverant (1960), who holds that "the behavioral realm typically ascribed to intelligence '[is] within the confines of modern learning theory, particularly a social learning theory."

A close examination of the views held by the proponents of each of these definitions would reveal that either (1) for those who make the simpler, more general statements, there has been little concern about or exploration into the details of the processes of intellectual function, or (2) among those who do try to understand the detailed processes, incomplete knowledge still forces them to make unverified assumptions. In the second instance there is always the danger of personal bias and preference in the assumptions made and in the consequent conclusions.

With the accumulation of recent empirical data it has become increasingly evident that mental abilities as measured by standard tests are a function of (or the end product of) many determinants. These determinants include, first, the human organism with its basic complement of neurons, sense-perceptors, motor reactors, hormones, enzymes along with their related organizing tendencies for action and reaction to the environment. There is much still unknown about the determinants of individual differences among all these—differences that may be a function of many things, including chromosome patterns, some of which now appear to be sex-linked. They may include complex inherent differences in rates of maturing of the various biological

structures and functions, as well as of their ultimate potential.

✓ (There is the possibility also of various kinds of prenatal and perinatal "environments" resulting in damage or interfering with the development of optimal function. Postnatally, there is a wide range of environmental factors which may alter differentially the manner and degree, at successive maturational stages, of the organism's utilization of its potential. These aspects of the environment may be classed in several ways, for example (1) enrichment versus impoverishment of relevant stimuli, (2) the specific relevance or lack of it, in terms of meaningful positive and negative "feedback," for specific behaviors, and (3) the emotional climate, which may be one of pervasive warmth and approval, fostering security, or it may be a climate of disapproval and hostility—conditions that tend to cause anxiety and insecurity, thus interfering with "clear-headed" reasoning, problem-solving, and curiosity, that is, an impetus to explore, to learn and to find answers to questions. On the physical side, (4) mental abilities may be adversely affected, either before or after birth, by nutritional deficiencies, severe infections, or genetically determined blood-group incompatibilities.) ✓

✗ Children's mental abilities, as measured by records of their performance, whether on intelligence tests, achievement tests, graded series of learned tasks, or other measures of specific abilities, are always end-products of the total prior complex of interactions among these multiple determinants. (It is to be expected that there will be differential effectiveness of these various causal factors, between different children, and at different ages, as well as among the different types of ability.) ✗ If we keep in mind the preceding list of complexities involved in the development of mental abilities, it becomes clear that those definitions of intelligence that stipulate *either* heredity *or* environment as its primary determiner, patently rest on false assumptions. ✗ On the other hand, broad definitions such as Thorndike's and Terman's do little more than orient us to the general class of mental processes under consideration, and those that refer loosely to the interaction of the growing organism with its environment add very little information about the specific determiners of intelligence.

There is, however, an increasing body of knowledge which, when properly integrated should afford us some understanding of the nature of mental abilities and the processes involved in their development

DEVELOPMENTAL ASPECTS OF MENTAL ORGANIZATION

(In the developing human organism the earliest behaviors are not clearly differentiated, but would seem to be the precursors of sensory, perceptual, and motor processes, and thus basic to developing mental abilities. The first action of the fetus is an independent motor function, the rhythmic heartbeat which occurs at about 3 weeks gestational age (Carmichael, 1954). Simple reflexes involving neural function have been noted first in the fetus at about 8 weeks (Hooker, 1943). By the time the infant is born, at term, he is equipped with some 27 reflexes, which serve to carry on the extrauterine processes of life. These include responses to the various organs of sense, vision, hearing, temperature, taste, equilibrium, touch, and pressure.)

The manner in which these earliest neuromuscular structures and functions develop has recently been described by Anokhin (1964), who summarizes a series of studies carried out in Russia and elsewhere, and presents a theory of systemogenesis as the regulator of developing nervous activity. Anokhin points out that for any species, certain adaptive functions must necessarily "be ready at the moment of birth." He goes on to cite experiments that show specific departures from the general rule of the cephalocaudal sequence of development proposed by Coghill (1929): development is most advanced at the head, and the temporal order of development proceeds from the head downward and from the body out to the extremities (hands and feet). Instead, as Anokhin points out, we find superimposed on this general trend another organizing principle. Neural fibers that had previously shown quite independent developmental processes will at a given stage grow rapidly and coordinate to produce a new functional unit. Such combinations occur repeatedly, each one timed to materialize at a particular stage in the developing organism, so that an appropriate (though often immature) reflex is functional at a crucial point in

the growth process. For example, the sucking reflex in the newborn involves the facial nerve. At a certain stage in development there is a rapid growth of those fibers that activate cheek muscles to contract in such a way as to permit suction, yet at the same time other facial muscles have not yet reached a comparable maturity of function. Another example is seen in the grasping reflex, which can be detected as early as the fifth prenatal month. In this instance the nerve that innervates the flexor muscles of the fingers matures before other nerves in the forearm.

Necessary for such a functional system is an integrative organization of the various parts, but also necessary are a receptive apparatus, and central as well as peripheral structures, which afford "an afferent feedback about the achieved final adaptive effect." "The functional system as represented in an adult does not appear from the beginning in mature form" but it "begins to play an adjusting role in the life of the newborn long before its complete and definite maturation." Although the studies he cites are primarily of the fetus and newborn, Anokhin (1964) proposes that the principles derived from them might well apply to postnatal development of the brain and its functions.

Certainly there is evidence that the processes of myelination of nerve fibers continue during the first 3 or 4 postnatal months (McGraw, 1943). During this period the infant's reflexive behaviors mature rapidly, and many of them are soon replaced by voluntary, more complexly adaptive responses. It may well be hypothesized therefore that such processes of neural integration relevant to developing mental abilities may continue to occur in later development, although at a much slower rate. The organizers of later neural integrations would probably be more complex and under different (perhaps enzymatic) controls.

Such a form of continuing neural integrative action, or "systemogenesis," would be congruous with available information on the behavioral aspects of developing mental abilities. That is, increasingly complex abilities with different mental "factors" emerge at successive points in the child's development. As long as these integrative neurological processes play a role in the developing organism, they may play a role in controlling

the rates at which mental growth occurs. This role could operate differentially among children with different inherent patterns of maturation. On the other hand, specific training (including practice) might also serve to speed up the processes of higher integration and thus allow the child to function at a more abstract level.

If, by inheritance of mental abilities, we mean that there are inherited individual differences in the facility and degree to which "systemogenesis" takes place, then the findings from studies of learning and of "impoverished" versus "enriched" as well as other types of environments would all fit into a reasonable pattern in which these inherent trends in maturation would be retarded or accelerated by relevant environmental conditions. Information about the relation to age of different kinds of mental ability, or "factors" of intelligence, may indicate the extent and manner in which such inherent neural integrative processes may continue over the life span.

INTELLIGENCE TESTS THE MEASURING INSTRUMENTS

The assessment of a child's mental abilities is made by means of carefully standardized tests, which are graded in difficulty. The items in these scales may be thought of as problems or tasks, and the solutions or correct responses to these items are samples of the child's capacity to think or to reason—that is, of his intelligence. The first of these scales, the Binet-Simon, was designed to assess ability to do schoolwork. In a general way, the character of the tasks set in those original tests has been maintained on subsequent tests. Problems of arithmetic, of verbal reasoning, of general information, of discriminating complex spatial relations, and the like, as well as vocabulary, are all carefully selected according to several criteria. The tasks must be of such a nature that they are approximately equally familiar (or strange) to all of the children in the population for which they are relevant. They must be reliable (i.e., they must yield stable scores that will be essentially unchanged on repetition of the test after a short interval). Each type of task must contain items ranging from relatively simple

increasing difficulty as measured by the scores earned by children of successively older ages. The tests must be "valid" measures of the mental functions they purport to test—a criterion that presupposes an agreed upon and consistently applicable definition of the term which designates the mental function in question. The tests must be administered in a standard way so that the problems set will be the same for all children who take them.

Finally, the norms or standards of the test scores must be based on tests given to a large number of persons, selected to represent the ages for which the tests are intended and the populations on which the tests are to be used. This reference population is usually selected to be a representative subsample of a country (say, the United States) in such matters as socioeconomic, demographic, and ethnic distribution. In other words, a standard test is meant to sample mental abilities in such a way that the scores of a given individual state his position relative to the average person the same age, and from the same general population, or else to a specified sample with known limiting characteristics. For an example of a limiting condition, tests may be standardized for use with blind or deaf children.

Mental tests are divided according to the manner of their administration into individual and group tests. The first tests were individual. That is, a test was given to each child separately by an examiner who asked questions and then recorded the child's responses, or supervised his drawings and written responses. This procedure insures the subject's greatest attention to and effort in appropriately carrying out the tasks at hand. It enhances the validity and reliability of the scores. However, it is a very time-consuming and therefore expensive procedure.

In order to obtain scores on large numbers of persons in a short period of time, the tests were adapted for group use. Printed forms and pencils could be distributed to an entire roomful, and the group could then be instructed to mark answers according to a formal set of directions. Group tests are widely used in schools, in military installations, and in other situations where it is important to test large numbers quickly. Group tests work best with testees who can read, who are

required, and who are well motivated to succeed. If the scores obtained are less accurate than those from individual tests, they nevertheless are adequate for assessing relative abilities or averages for groups (e.g., a school population). They also are useful screening devices: the few persons whose scores are very low or very high on a group test can then be tested individually to obtain more accurate evaluations of their capacities.

Individual Tests

Probably the best-known and most-used individual intelligence test in the United States is the Stanford-Binet. This revision of Binet's French tests was first published in 1916 by Lewis M. Terman. It was quickly adopted by psychologists and educators and soon became widely used. This test covered the ages 3 to 18 years; the items were arranged by age, according to their difficulty, with six tests at each year through age 10, after which tests were set at 2-year intervals with eight items at year 12, and six at each of years 14, 16, and 18. Mental ages were calculated on the basis of the number of tests passed, each item weighted according to the number of tests at the age-level. That is, each 6-year item is worth 2 months' credit, a 12-year item counted 4 months, and so on. The total months credited, including the first 3 years and all items passed, became the *mental age*. Mental age (MA) divided by the child's *chronological age* (CA) gave the IQ, or *intelligence quotient*. For persons 16 years and older, 16 years was used as the CA for obtaining the IQ. This general procedure for obtaining scores on the intelligence tests had grown up gradually, from the earlier versions of the scale. Another revision of the Binet Scale was made by Kuhlmann (1912), and for a time it had considerable use, in part because it included tests for infants at 3, 6, 9, 12, 18, and 24 months. However, it soon lost out to the Stanford revision, which was simpler to give and score.

In 1937 Terman and Merrill published an extensively revised Stanford-Binet with two equivalent forms, L and M. This revision covers the ages 2 years to superior adult, although in contrast to the main portion of the scale the standardization was less adequate for the 2- and 3-year tests. Another revision, in 1960, updates some of the materials, and

offers a single form, L-M, which is a selection of the best parts of scales L and M and with improved norms for years 2 and 3.

In this newest revision, the CA/MA ratio was dropped as the method of obtaining the IQ. Instead, deviation IQs were derived from the means and standard deviations of the mental age scores obtained for the standardization sample, at each year in childhood and in the tested sample of adults. In this way the authors followed procedures which had previously been established for tests of adults, whose scores on mental tests change very little with increasing age.

The concept of mental age had grown out of the finding that school-age children's performance on the tests increases at a steady rate in relation to their chronological age. However, at a stage somewhere near 13 to 16 years, the rates of mental growth diminish and the yearly increments in mental ability grow smaller. Clearly a year of mental growth is not the same at all ages. For example, the change from 15 to 16 years is not the equivalent of the change from 9 to 10 years. The use of standard scores based on a person's standing relative to his age-peers yields the most adequate measure of that person's relative intelligence at a given time, and of the stability of his mental growth as measured in tests at different times. It avoids the difficult problem of adjusting for unequal rates of mental growth at different ages.

With increasing use of intelligence tests, not only for children, but also for adults, a number of both individual and group tests were designed for the purpose of testing adults. These tests served two purposes. Their content was specifically appropriate for adults and consequently appealed to them and resulted in good motivation to succeed. Also, in contrast to the earlier scales for children, the new tests were designed to have more "top"—that is, to include more difficult tasks, which tapped the more abstract mental processes. The added levels of difficulty produced a relatively discriminating instrument for identifying highly intelligent adults.

Of the adult individual tests the best known and most widely used are those of David Wechsler. The first version, published in 1939, known as the Wechsler-Bellevue Intelligence Scale (W-B), has norms for ages 10 through 49 years. The W-B is composed of 10 sub-

scales, 5 verbal and 5 performance, plus an eleventh vocabulary subscale. The raw scores on each subscale were converted to scale scores on the basis of the means and SDs (standard deviations) of the total tested population ($n = 1750$), which ranged in age from 7 to 65 years. These scale scores were then summed to give point scores for the 5 verbal, the 5 performance, and the 10 full-scale tests. Vocabulary could be treated as a separate scale or, by prorating the scale scores, included in the verbal scale. IQs were obtained for successive ages by conversion from standard scores based on the means and SDs of point scores at each age interval. The mean point score was assigned an IQ of 100, and each standard deviation from the mean was equated to 15 IQ points. This is in essence the same procedure that has been used for most adult scales, and which (as we have noted) was later used for obtaining IQs in the 1960 Stanford-Binet.

Since the original 1939 scale, Wechsler has published a number of scales of intelligence, all of them along the same general plan, and all tests to be administered individually. Form II of the W-B was published in 1946, for use as an alternate form of the scale for adults. This form of the scale was later extended downward to approximately 5 years and published in 1949 as the Wechsler Intelligence Scale for Children (WISC). The 1955 Wechsler Adult Intelligence Scale (WAIS) is a revision of the original W-B form I. Among other changes, this revision extends the upper levels of the scale to include more difficult items, and thus in comparison with the original version permits more discriminating scores among adults of superior intelligence. This revision also is standardized on a more adequate sample of older people, and includes norms for scoring at ages 16 to 74 years and over. The latest in this series of scales, the Wechsler Preschool and Primary Scale of Intelligence (WPPSI) was published in 1967. Designed for use with young children, this scale has norms for scoring at 11 ages from 4 to 6½ years. Wechsler states (1967) that about 4 years is the youngest age at which one can, as a practical operation, obtain a measure of "global intellectual capacity" by using tasks the same as or similar to those he includes in his scales at later ages. The three most recent of his scales, the WPPSI, the

WISC, and the WAIS, together afford measures of intelligence for most of the life span. The lowest age and score possible are for a 4-year-old with an IQ of 45.

These Wechsler scales differ from the Binet scales in furnishing subscores at all ages for each of 10 or 11 different aspects of intelligence, as well as IQs for verbal and performance subscales and Full Scale (global) scores. The nature of the abilities measured is indicated by the names of the subscales. The Verbal subscales are Information, Comprehension, Arithmetic, Similarities, Digit Span (or Repeated Sentences), Vocabulary, Digit Symbol (or Animal House), Picture Completion, Block Design, Picture Arrangement (or Mazes), and Object Assembly (or Geometric Design). The titles in parentheses are for the WPPSI scales for children 4 to 6 years of age. Although these subscales were not selected to represent statistically determined discrete factors, they lend themselves to factor analysis, and perhaps deceptively (because their reliability as independent scales is low), they offer the possibility of drawing for each person a "profile" showing the more and less advanced aspects of his mental abilities. The tests can be administered with comparative ease and speed, because the examiner moves rapidly from one test series to another, as the testee reaches his capacity on each. For these reasons the scales have caught on rapidly and are widely used. They do not, however, give IQs at the extremes of high and low capacity, and they are not applicable to infants and children under 4 years of age. For these reasons, at least, they cannot entirely replace such tests as the Stanford-Binet.

There are in this country several individual tests of mental abilities for infants. As has been noted, the Kuhlmann-Binet included some tests for infants, starting at 3 months, whereas the Stanford-Binet (1937 and 1960 revisions) starts at 2 years. Among tests specifically designed to assess mental ability in early infancy, Gesell's is the first (1925, 1928) and best known (e.g., *Developmental diagnosis*, 1962). Another, widely used, is Psyche Cattell's Mental Test for Infants and Young Children (1940, 1960). Bayley's California First-Year Mental Scale (1933) and Infant Scale of Motor Development (1936) have been revised and published as the *Bayley Scales of Infant Development*. For babies 2 to

30 months of age (1969) The Griffiths scale, *Abilities of Babies* (1954), is standardized on an English population Other tests by Charlotte Buhler (1930), by Linfert and Hierholzer (1928), and by Gilliland (1949b) are of historical interest but are not in current use Graham, Matanlatzo, and Caldwell devised a scale for assessing neonates 5 days or younger (1956) On this scale, scores are obtained for Vision, Muscular Tension, Maturation, Pain Threshold, and Irritability Rosenblith has revised the scale (1961) and is using it in a series of researches

Infant scales, by the very nature of the young human's level of functioning, must be administered individually Also, at these early ages, there are inherent problems in subdividing the tests into different mental abilities, as well as in the procedures of testing and scoring

Gesell's scales were first reported in 1925 and he published a series of books, successively clarifying the details of administering the tests and evaluating the scores, eventuating in the book *Developmental Diagnosis* (latest edition, 1962), which is essentially a manual for their use The Gesell scales give norms for "key ages" at weeks 4, 16, 28, 40 and months 12, 18, 24, and 36 For each of these key ages behaviors are given, by 4-week intervals, for ages below and above the key for the first 56 weeks, and for 3-month intervals, 15 to 24 months and every 6 months to 42 The behaviors at each age are divided into four categories Motor, Adaptive, Language, and Personal-Social The Motor behaviors consist of body control, manual coordination, creeping, walking, balance, and jumping—behaviors which are not ordinarily classed as mental The Personal-Social items are for the most part scored on the basis of an interview with the mother They include trained behaviors such as feeding self, toileting, dressing, and communications such as asking for things and comprehending demands The tested (observed) mental responses are those classed as Adaptive and Language Adaptive items include looks at, reaches for, grasps, or manipulates a rattle, ball, or 1-inch cube, builds a tower of two or more blocks, puts blocks in form board, etc Language items include "alert expression," coos, polysyllabic vowel sounds, says dada and mama, uses other words, names, and points to objects and pic-

tures) Developmental ages are given by the examiner according to his general impression of the infant's responses and the age-level of response which is most characteristic The norms are derived from a small longitudinal sample of middle-class New Haven babies, with the number of children tested at any one age varying between 26 and 49 in the first year and between 18 and 60 for the preschool ages

The Cattell Infant Intelligence Scale utilizes many of the Adaptive and Language items from the Gesell scales The format of this scale is patterned after the Stanford-Binet, and may be thought of as a downward extension of the 1937 Form L of the Binet Tests start at 2 months, with five tests at each age, monthly through the first year, bi-monthly in the second year, and then at 3-month intervals to 30 months Between 22 and 30 months items from the Stanford-Binet are intermingled with other items designed by Cattell These tests are standardized on the infants in the Harvard Growth Study conducted by Dr Harold Stuart (1939) The subjects were seen at 3-month and then 6-month intervals, the number at any one age ranging between 20 and 67 Because of the interval between tests, the placement of many items was made by interpolation Mental ages and IQs are determined by the original method of the Stanford-Binet

The original versions of the Bayley Mental and Motor scales, like the Gesell and Cattell scales, were derived from scores earned in a series of often-repeated testings on a longitudinal sample This sample of 61 infants was somewhat above the average of the Berkeley, California, population in 1928 The parents' education ranged from 3 to 19 years, with a mean of 13.7 The children were tested monthly from 1 to 15 months with a few absences at most ages The number tested at any one age ranged from 46 to 61, with a mean *N* of 54 In the revision of these scales, the preliminary standardization, 1 to 30 months was based on 1700 Mental and Psychomotor tests, for 1500 of which the Infant Behavior Record was also scored The final standardization is made from tests on a representative U S sample, of 1262 children, about one third of which are drawn from the 1500 complete tests of the preliminary standardiza-

tion These form a strictly cross-sectional sample

Many of the test items and materials are similar to those found in other scales In the revised form practical improvements have been made on the materials (e g, wherever feasible, more durable and washable plastic has replaced wood), much care has gone into details of placing individual items on a scale of difficulty, and in clarifying the directions for administering and scoring The materials in the Mental scale were selected to elicit adaptive responses, including such behaviors as attending to visual and auditory stimuli, grasping, manipulating and combining objects, shaking a rattle, ringing a bell, interacting with the examiner by smiling, cooing, babbling, imitating, following directions, relating to toys in meaningful ways (e g, putting cubes in the cup, banging spoons together), showing memory or awareness of object constancy (e g, looking for a fallen toy, uncovering a hidden toy), goal-directed persevering tasks such as placements of pegs in pegboard, completing simple form boards, and following directions involving correct use of object names, prepositions, and a concept of "one"

The Motor scale includes such abilities as holding the head up, turning over, sitting, creeping, standing, walking, going up and down stairs and manual skills such as grasping small objects and throwing a ball

The Mental and Motor scales are scored separately raw scores composed of the total number of items passed are converted to mental (or motor) ages and to MDIs (Mental Development Index) or PDIs (Psychomotor Development Index) These indices are derived from the means and SDs at each age for the standardization sample

The Infant Behavior Record is filled in immediately after the mental and psychomotor tests are completed It is composed of ratings of such general behaviors as responsiveness to persons and toys, happiness, fearfulness, reactivity, endurance, and goal directedness There are age norms expressed in terms of the most characteristic ratings at each age

In their revised form, the Bayley scales are based on both a larger and a more representative sample of infants than is true of previous infant scales Therefore they

should form a sound set of current standards for evaluating development in the first 2 years As of 1969 studies of the development of mental abilities in the first 2 years are, in most instances, dependent for their normative reference points on the earlier scales, whose age-placements are derived from small, selected samples

Group Tests

Among the first group tests of intelligence are the Army Alpha and Beta tests, which were widely used for testing during World War I These tests, their revisions, and others derived from them, have continued in use with adults Among the first group tests for children are the Pintner General Ability Tests (1923) and the Pintner-Cunningham Primary Test (1927) Pintner's earlier work had formed the basis of the Army Alpha and Beta scales, and with colleagues he went on to develop similar scales for use in the schools

From this start, many group tests were developed An early one by E L Thorndike (Thorndike, 1926, Thorndike, Woodward, and Loige, 1935) called the CAVD (Completions, Arithmetic, Vocabulary, and Directions), has norms for 3 years to superior adult The Miller Analogies Test (1960) is designed for testing college students, and Terman's Concept Mastery (Synonym-Antonym and Analogies) Test (1956) is designed for testing superior adults Thurstone's Primary Mental Abilities Test (1938, 1947, Thurstone and Thurstone, 1943, 1958) pioneered the way in devising group tests on the basis of factors derived from statistical analysis of test contents

Group tests proliferated and soon became the bases for many statistical studies of mental abilities Because of the ease with which scores for large samples can be obtained with group tests, they lend themselves well to such analyses Some representative scales will be referred to later in a discussion of factors of mental abilities

BASES FOR THEORIES OF INTELLIGENCE

The foregoing "intelligence tests" in their various forms are the available tools for measuring, or it may be more accurate to say sampling the mental abilities of persons

at various ages and degrees of maturity. As noted earlier, the processes through which the human organism develops from concrete to increasingly abstract mental functions, as measured by the tests, are clearly a function of the interactions of the organism with his environment. The various theories of the nature of intelligence have grown out of differing interpretations of the relevant characteristics of both the organism and the environment. To a considerable extent the amount and kind of information the theorist has about either or both will determine this theory.

Early theorists such as Galton (1869), G. Stanley Hall (Prueett, 1926), Burt (1934), Terman (1916), and Gesell (1962) most often classed intelligence, along with other characteristics both mental and physical, as being genetically determined. It was noted that not only did the shape of one's ears or the tendency to hemophilia run in families, but so also did a tendency to "genius" or to "feeble-mindedness." The evidence adduced for the hereditary nature of mental abilities was at first very crude, and did not take into account many possible influences of the environment.

The findings from intelligence test scores, in their first applications, gave corroborative support to Galton's studies of family resemblances. Outbit (1933), for example, obtained correlations between test scores of children and their parents of .61 to .76 on a sample of 51 families with 257 tested children. Conrad and Jones (1940), who tested an entire Vermont community, obtained parent-child correlations of .49 for an N of 501 parent-child pairs. These correlations are representative of those obtained by other investigators of the relation between parents' and children's intelligence, or between parents' education (as an approximate indicator of ability) and their children's IQs.

Another kind of evidence, from early studies, which favored the hereditary interpretation of intelligence came from studies of retests of children after a lapse of time. In a number of instances children (usually of school age) were retested after several months or a year or longer. The average change from test to retest was about 5 IQ points, a change which could be accounted for by the imperfect reliability of the instruments used. In

these first studies of the constancy of the IQ, there had been no control over such important variables as the age at testing or the time-interval between test and retest.

On the basis of the findings from these early studies, there was a widespread concurrence among educators and psychologists in the belief that intelligence is a general, inherited ability that increases in amount with growth. The growth of intelligence was seen as stable, that is, the IQ was held to be constant. Any changes in a child's score over time were attributed to imperfections in the testing instrument or the manner in which the test was given.

There were, however, some early signs that individual children's scores did not necessarily follow this principle of the constant IQ. Baldwin and Stecher (1922) reported a detailed and careful study of repeated tests on the Stanford-Binet, on 143 children tested once a year at irregular intervals between the ages of 5 and 16 years. They found that the mean IQ increased with age and with repetitions of the test. They noticed, also, that the correlations between first tests and successively later tests became progressively smaller.

Bayley's (1933a) study of mental growth in the first 3 years, by repeating tests on the same children, showed that the infants grew very rapidly in mental abilities but that there were great individual differences in their rates of growth. Tests were given at regular intervals, monthly 1 to 15 months then tri-monthly to 3 years. Then scores during the first 6 months were entirely independent of scores at 2 or 3 years, and even at 10 to 12 months the correlation with 3-year intelligence was only .45. Since that time other studies (Honzik, Macfarlane, and Allen, 1948; Hindley, 1960; P. Cattell, 1940) repeatedly show that scores on tests during the first 2 years are correlated very little or not at all with scores earned at 4 years or later. These findings raised a series of questions about the reliability and validity of infant tests and about the nature of the developing mental functions in infancy and early childhood (Stott and Ball, 1965).

In recent years there has been renewed interest in Piaget's theory of the stages of developing intellect and of the possibility of accelerating the rates of progress through these stages. The findings from animal re-

search on the effects of environmental deprivation in infancy (Bennett et al, 1964, Freedman, 1958, Harlow, 1962, Scott, 1958, 1963) led to investigations of deprivation (institutionalism) on human infants (Bowlby, 1952, Biedbeck and Irwin, 1946, Fischei, 1952, Gilliland, 1949a, Goldfarb, 1945, 1955, Levy, 1947, Moore, 1947, Rheingold, 1961, Spitz, 1945 Woodworth, 1941) Factor analyses were made of infant tests in efforts to differentiate early mental processes and to seek out possibly more adequate predictors of later intelligence (Cameron, Livson, and Bayley, 1967, Richards and Nelson, 1939, Stott and Ball, 1965) All of these approaches have resulted in increased knowledge about the processes of early mental development, and their causes genetic, congenital, and environmental

There are those (e.g., J. B. Watson and B. F. Skinner) who say that we can only know about an organism's mental processes from his behavior. If this is true, then (it is argued) all we need concern ourselves with is the observed behaviors and the ways they can be controlled and changed by carefully designed experiments. Because the human organism is flexible, and learns readily, experiments designed to produce learned or conditioned responses (Watson) or operant conditioning (Skinner) as a rule yield results in the form of adaptations appropriate to the child's environment. It is an easy next step to conclude that mental abilities are purely a function of learning, and that therefore individual differences in intelligence result entirely from more or less adequate opportunities for the infant and young child to learn.

Hunt's (1961) position, as stated in the definition quoted earlier, is strongly influenced by this kind of thinking. He points to the more advanced behavior of animals and children who have been trained to make appropriately adaptive responses, and he shows that experience is necessary for the child to have learned the more advanced or abstract forms of thinking. That is, a child learns to read, and with this reading ability as a tool he can learn many more things. Hunt's position is developed not only from the effects of specific learning experiments, but to a considerable extent by studies of the damaging and retarding effects of environmental impoverishment, on both animals and humans.

The general consideration of the depressing role of environmental impoverishment has, as its corollary, the importance of enrichment of the environment to secure optimal mental abilities. The questions about the divergent effects of contrasting amounts of stimulation lead to at least two further broad questions that need to be answered if we are to understand the role played by the environment in mental growth. The first of these is a need to identify and understand those aspects of the environment to which infants and children at different ages respond differently or not at all. The second question is whether there are what some have referred to as "critical periods." That is, are there specific ages or stages in the child's development at which certain aspects of his environment are crucially important in determining later mental abilities? Or, from a somewhat different assumption, in order to maximize all children's abilities, is it necessary to insure that each child has, from the very start of life, the best possible environment—if we can know what that is? To what extent can a child recover from earlier impoverishment? And is there somewhere during growth a "point of no return?" That is, what are the conditions that permit recovery? How do they relate to the length of the period of impoverishment, and to its intensity?

To date, few if any definitive experiments have been made that can give us clear answers to these questions. However, there is a considerable body of information about the relation between test scores and various aspects of the environment. From what we now know, it should be possible to construct a rough map of the kinds of stimuli (environmental variables) that are related (perhaps causally) to mental abilities at successive ages. There is also some material that is relevant to the persistence of the effects of earlier experience on later functions.

THE EVIDENCE FROM LONGITUDINAL STUDIES

When the same persons are tested repeatedly over time, it becomes possible to identify those changes that are clearly functions of developmental changes and processes of organization within the individual. It is, furthermore, possible to study individual dif-

ferences in rates of mental growth, not only of global "intelligence" but also of different types or factors of mental ability. It also affords knowledge of stability and change in mental abilities, and indicates the conditions and limits of predictability over time of the IQ, that is, of relative performance on tests of intelligence.

In interpreting these longitudinally observed processes, however, it is necessary to take cognizance of some limitations which are inherent in the longitudinal method. As a safeguard against possible methodological errors, checks can often be made by posing relevant questions to analyses of cross-sectional data—that is, data collected once from a sample composed of subjects of different ages. The two methods can, in this way, serve to check each other in testing theories that originally derive from either method.

Specifically, the problems arising from the longitudinal method are related to both sampling and practice effects. The sampling difficulties are of several kinds. First, such studies usually must rely on voluntary cooperation of the subjects, thus only those who are interested and willing participate, and such willing samples presumably leave out an important segment of the population. The alternative, a captive audience (as a rule, inmates of an institution), is atypical in a different way. Another problem is sample attrition. Not only does the size of the sample diminish over time, but one must be concerned with the possibility that the attrition is selective in important ways. For example, the more restless migrant subjects may leave, the less healthy may die, and the less able or less educated may more often become reluctant to participate. The investigator must therefore be aware of these limiting conditions, test their relevance to his own materials, and be cautious of generalizing his findings beyond the kinds of sample he is studying. Nevertheless, there are enough differences among longitudinal studies, in the extent to which specific sampling limitations occur, so that often the various studies can be used to cross-validate each other. Furthermore, these problems of sampling errors can often be resolved by comparisons with findings on the same tests from an appropriately selected cross-sectional sample both larger and more representative of the general population.

The same kinds of checks and balances can be applied to study the effects of practice or general familiarity with the tests and testing procedures—conditions that are inevitable in longitudinal samples. For such checks, comparisons can be made with appropriately matched cross-sectional samples composed of subjects who are not familiar with the tests and procedures of the longitudinal program.

✓ STABILITY AND CHANGE IN MENTAL GROWTH RATES

As already noted, starting with the pioneering work of Baldwin and Stecher (1922), a series of studies utilizing repeated tests of the same children over time has gradually eroded the belief in the "constant IQ." In an early report, Furfey and Meuhlenbein (1932) obtained negative correlations between Stanford-Binet IQs at 4 years and scores on the Linfiet and Hiehholzer test (1928) for groups at ages 6, 9, and 12 months. These r s of -11 , -34 , and -20 for the three ages were attributed to unreliability or invalidity of the infant tests. Shortly after this Bayley (1933a) reported a detailed analysis of mental tests given to a longitudinal sample of 54 to 61 children at 20 ages, between birth and 36 months. Again, small negative correlations (-04 and -09) were found between 1-, 2-, and 3-month tests and tests at 18 to 36 months. A later report (Bayley, 1949) on these same children shows r s with the 4-year test of -21 for the 1- to 3-month scores, -16 for the 4- to 6-month scores, $.02$ with 8-month, $.27$ with 11-month, $.35$ with 14-month, and $.49$ with the 21-month level of tests. The 3- and 4-year tests correlate generally higher with tests at later ages, through 18 years. These latter r s range between $.82$ and $.46$, their size depending largely on the elapsed time between tests.

Analyses of Bayley's First-Year Mental Scale show reliabilities to be adequate when equal halves of the scale are correlated and corrected by the Spearman-Brown formula. These correlations average $.82$ but were lowest in the first 3 months ($.51$ to $.74$, with an estimated reliability of the combined scores for months 1, 2, and 3 of $.84$). For ages 4 to 36 months the single-month, split-half reliabilities range from $.75$ to $.95$ (Bayley, 1933a). Similar reliabilities have been

reported for other mental test scales, which measure abilities in the first 3 years of life (Werner and Bayley, 1966). Thus the lack of stability in the first 3 years cannot be attributed to poor reliability of the measuring instrument.

The findings of these early studies of mental growth of infants have been repeated sufficiently often so that it is now well-established that test scores earned in the first year or two have relatively little predictive validity (in contrast to tests at school age or later), although they may have high validity as measures of the children's cognitive abilities at the time.

Moreover, a careful look at individuals' growth in intelligence after 4 or 6 years has revealed many instances of changing IQs at all ages. Even though the rates of growth in intelligence, and consequently the IQs, are relatively stable in most persons after 6 years, various investigators have reported widely divergent growth patterns among individual children. There are always in the reports a few children who evidence large shifts in IQ. Among these studies are those of Dearborn and Rothney (1941) on the Harvard Growth

Study, Honzik, Macfarlane, and Allen (1948) on the Berkeley Guidance Study, Sontag, Baker, and Nelson (1958) on the Ohio children of the Fels study, Hilden (1949) on the Denver children studied at the University of Colorado Child Research Council, Freeman and Flooy (1937) on Chicago children, Ebert and Simmons (1943) on Cleveland children, and Bayley (1940, 1949) on the Berkeley Growth Study.

Examples of individual growth in intelligence over time are given for the Berkeley Growth Study in Figs 1 and 2. The scores in these two figures are standard scores, based on the means and SDs of mental ages for this sample. Therefore changes in scores represent changes in ability relative to the other members of a stable, frequently tested population. Cases for whom there are 36-year records have been selected to represent the brightest and dullest of each sex as well as several with intermediate intelligence.

GROWTH IN MENTAL ABILITY AFTER SIXTEEN YEARS

The longitudinal method has also produced new information on age changes in intelli-

Fig. 1 Individual curves of relative intelligence (standard deviation scores) of five males, birth to 36 years, Berkeley Growth Study cases

Fig 2 Individual curves of relative intelligence (standard deviation scores) of five females, birth to 36 years, Berkeley Growth Study cases

gence of adults, that is, the age at greatest ability (i.e., at which highest test scores are obtained), and the extent to which intelligence levels are maintained during middle and old age. When the mean test scores of a large sample of adults were computed for subsamples of increasingly older ages, such investigators as Miles and Miles (1932), Jones and Conrad (1933), and Wechsler (1944) showed the highest scores occur in the early twenties, decreasing thereafter. In contrast to these reports, the results of recent longitudinal testing of adults (Bayley, 1955, 1957, 1966a, Bayley and Oden, 1955, Freeman and Flory, 1937, Owens, 1953) have challenged this concept that growth in intelligence stops at an early age and then declines. (The ages given for cessation of growth have varied from 13 to 21 and more recently to 30 years, see Miles and Miles, 1932, Jones and Conrad, 1933, Wechsler, 1944, 1958.) However, when the same subjects are retested over age spans extending in some instances to 50 years, the scores have continued to increase, more clearly so for tests of verbal knowledge and information. Freeman and Flory (1937) were among the first to report increased scores through 21 years for a small selected sample of college students whom they

had tested as children. Owens (1953) was able to locate and test 127 50-year-olds on the same Army Alpha Intelligence test they had taken as 19-year-old freshmen at Iowa State College. Their scores at 50 years were significantly higher than their scores at 19. Bayley and Oden (1955) reported on adult tests given 12 years apart on 768 subjects of Teiman's "gifted" (IQ 140 to 200) sample and 335 of their spouses. When the samples were divided by age into 5-year samples, it was found that on the retest the scores had increased for all age groups for both sexes and for both the gifted sample and their spouses.

Bayley (1966a, 1968a, 1968b) has recently extended the Berkeley Growth Study growth curves through 36 years. As measured on the Wechsler adult scales (W-B at years 16, 18, 21, and 26, WAIS at 36), the scale scores increase through 26, after which age for the full scale score and total sample, scores level off and remain unchanged through 36 years. When the "absolute scale" growth curve developed for the BGS sample in "16D" units (Bayley, 1955) is now extended to 36 years, the result is the curve shown in Fig 3. The mean score shows no change after 26 years. However, there are increments after 26 years in the males' scores on the verbal scale. The

Fig 3 Theoretical curve of the growth of intelligence, based on data from the longitudinal Berkeley Growth Study. The units of growth (16D scores) are derived from a modification of Thurstone's method of absolute scaling (See Bayley, 1956)

female scores either actually drop (Performance scores) or remain unchanged (Verbal scores) between 26 and 36 years.

Birren (1968) reports from studies of elderly men that there was very little deterioration in intelligence scores of those who were in optimal health. However, for some who were found to have subclinical disease, the scores were significantly lower. On a retest 5 years later, some showed no change in scores, whereas others showed considerable change. Precipitous drops in this instance were related to deteriorated health. Birren makes an important observation that the average changes in scores do not represent a general trend for small drops but include some cases that do not change and others who change markedly. That is, the rates of growth and decline in individuals vary with both internal and external factors—in this case with health.

GROWTH RATES AT DIFFERENT LEVELS OF ABILITY

The subjects of the longitudinal studies on which most of the foregoing reports are made were selected, to varying degrees, as above-average or superior in intelligence. However, several investigators have reported increased adult IQs among populations who as children

were classified as average (Charles and James, 1964) and retarded (Charles, 1953; Baller, 1936, and Miller, 1965). Bayley (1968a) found continued increases in scores through 36 years for the lowest-scoring half of the Berkeley Growth Study sample. The increase was found for the lowest-scoring male, whose IQs on the Wechsler scales increased from 64 at 16 years to 80 at 36. McCulloch (1957) found evidence of increased scores on verbal tests through 30 years or longer in mentally retarded institutionalized adults. Thus there is ample evidence that some kinds of intelligence increase well into middle age and perhaps beyond, not only for the bright but also for the "dull." It may be that those whose intelligence does *not* increase after 26 years are for the most part women. Bayley and Oden (1953) in their study of highly intelligent subjects found greater increases in men, through 50 years, and Bayley (1968b) found slight decreases in the Berkeley Growth Study women's scores after 26 years.

AGE CHANGES IN MENTAL ORGANIZATION

The failure in predictive validity from the infant tests has focused attention on the need to learn more about the earliest levels and presumably the more simple processes of

mental growth. There is a felt need to know more about the nature of mental processes in infancy, about their determining conditions both genetic and environmental, and the ways in which these determining conditions operate to enhance, retard, and in various ways alter mental development. Investigation of these processes includes not only study of the intelligence tests as such, but also inquiries into the nature of cognition, attention, and learning, and their bearing on general intelligence.

Bayley, in 1933, concluded that "the low correlations between scores made during the first year and those made later force one to the conclusion that superiority in one function does not insure superiority in the subsequent development of more complex functions."

There was no evidence for a general factor of intelligence during the first 3 years, but the findings indicate, instead, a series of developing functions, or groups of functions, each growing out of, but not necessarily correlated with, previously matured behavior patterns." Later (1949, 1955), Bayley extended this reasoning to apply to mental development over the whole growth period. She suggested that the lack of consistency over time in mental test scores reflects a series of changes in the nature of mental processes as they progress from simple sensorimotor adjustments to increasingly complex forms of adaptations, generalizations, abstractions, and their accompanying reasoning processes. Piaget's theory of the stages of intellect (1952) similarly represents a developmental pattern of changes in reasoning processes from the concrete to the abstract. Bayley's findings are congruent with Piaget's, and from the theoretical position of either there is no logical necessity that the adequacy of function at the simpler level will predict a child's abilities in the more complex thought processes at a later time.

The fact that after infancy rates of mental growth continue to exhibit variable individual trends calls our attention to a need to consider age changes in mental organization throughout the life span, and to inquire more carefully into the nature of the various mental processes which are classed as "intelligence."

Early efforts to study different kinds of mental ability were made by setting up separate scales each composed of series of tasks which were judged on a priori grounds to tap

different intellectual processes. Such scales did show differing rates of growth. For example, Freeman and Flory (1937) obtained separate scores for each of four scales: Vocabulary, Analogies, Completions, and Opposites (VACO). The Vocabulary scale they used was taken unchanged from the 1916 Stanford-Binet test. The other scales were adapted from scales that were available in 1921. For each of the four scales, they developed mental age units based on the performance of their 8- to 18-year sample. Freeman and Flory found, in this longitudinal sample, different rates of growth in scores for each of the four scales. When Conrad, Freeman, and Jones (1944) converted the scores from that study to comparable standard deviation scale units, the growth rates between 10 and 16 years were found to be greatest for Completions, second for Opposites, third for Vocabulary, and least for Analogies. In a like manner, the subscales for the Army Alpha were treated separately by Jones and Conrad (1933), and were found to show different age-trends in their scores. They found that scores in tests of Information and Vocabulary held up better in aging adults than scores on Arithmetic and Reasoning. Clearly, mental growth is a function of the kinds of ability tested, as well as of the age and kind of person.

However, the unreliability of scores on subscales of such tests as the preceding, among them the various forms of the Wechsler adult and children scales, make them of little or no use for evaluating the abilities of any one person.

FACTOR ANALYSIS AS A TOOL FOR STUDYING MENTAL ORGANIZATION

Consequently, investigators concerned with this problem sought a way to build up more reliable measures of the various kinds of mental ability. The statistical method of factor analysis was found most useful for selecting tests which were highly intercorrelated and which therefore might be assumed to measure the same "factor" in intelligence. Spearman (1904, 1927) pioneered much of this work. In an early analysis he derived a large general, or pervasive factor, which he called *g*, and several smaller or specific factors, which appeared to vary with the specific content of

the test involved. These might, for example, be arithmetic, memory span, spatial discrimination, or perhaps even musical ability. L. L. Thurstone (1947) did much to develop the factorial method to identify different mental abilities. He derived a number of independent factors, and he used these to develop scales for measuring more adequately the several factors. From a nucleus of a few similar items, it was possible to select and test additional likely items to build up reliable batteries of tests. Thurstone and Thurstone (1943, 1958), using this procedure, devised and standardized tests of Primary Mental Abilities. Their primary factors are Verbal Comprehension, Word Fluency, Number, Space, Associative Memory, Perceptual Speed, and Induction (or General Reasoning). Others whose work in this field is prominent are Guilford (1956), Tryon (1935), R. B. Cattell (1957), and Vernon (1960).

Each method has proved to be fruitful in identifying factors or clusters of related items which can then be used as criteria for developing scales of the various mental abilities. As these tools became increasingly sophisticated, increasingly adequate scales were developed. These in turn permit the study of growth rates and of individual stability of scores in the various abilities for different samples of subjects and for different environmental conditions. Such factorial scores also make possible the study of age-related changes in the relative contribution of different mental abilities to general intellectual functions.

The Thurstone Primary Mental Abilities tests have been developed for use in the elementary school grades. Both R. B. Cattell (1957) and J. P. Guilford (Guilford, 1956; Christensen and Guilford, 1955-1956; Hertzka and Guilford, 1955) have utilized factorial material in developing mental tests for adults.

One of the earliest factor analyses of infants' mental test scores was done by Richards and Nelson (1939). Using the Gesell scales at ages 6, 12, and 18 months, they derived a general factor and two additional factors which they called *Alertness* and *Motor Ability*. Since the items from all four of the Gesell scales were included in the analysis, the result, insofar as they might identify factors of mental ability, is of little or no value. For example, such motoric items as "walks alone" and "bowel control" are included as well as

the more usual mental items such as "says three words" and "looks for fallen spoon." None of the factor scores they derived proved to be predictive of later intelligence.

Recently Stott and Ball (1965) made a meticulous analysis of scores from 14 studies utilizing five mental scales applied to samples ranging in age from 3 months (P. Cattell) to 5 years (Stanford-Binet). The other scales included are the Bayley California First-Year Mental Scale, the Gesell Developmental Schedules, and the Merrill-Palmer Scale (Stutsman, 1931). In analyzing these infant scales, Stott and Ball used Guilford's Structure of Intellect (1956, 1957) as a frame of reference. Guilford, through factor analyses of test scores on adults, identified five categories of operations which he conceives as constituting the basic kinds of mental processes, or operations of the intellect. The three "thinking abilities" are Cognition (the discovery of new and recognition of old information), Production (the use of information to effect certain outcomes), and Evaluation (decisions as to the goodness, accuracy, or suitability of information or products). Production is further divided into Convergent Thinking (where there is one unique answer or conclusion to a problem) and Divergent Thinking (for which multiple answers may be appropriate). The fifth general factor of intellect in this structure is Memory. Each of these general factors can be divided into more specific abilities. Guilford's factorial structure is three-dimensional and he identifies 44 specific factors of a theoretically possible 72. It is interesting to see to what extent the factors derived from infant test scales can be fitted into Guilford's structure.

Stott and Ball (1965) have presented in Table 1 their summary of the infant scale factors at nine ages (3 to 60 months). As we see from this table, which utilizes the Guilford structure of intellect classification as a base, they were able to show loadings at various ages for all five classes of factors plus a few additional ones. Also, at one age or another for at least one test, 31 of Guilford's specific factors are represented. (For identification of these specific factors see Guilford, 1956, 1957.) For the 3- and 6-month tests they found loadings on four of the five classes: Cognitive, Divergent, and Convergent Production, and Evaluation. For one Gesell item at 6 months, but more generally at 12 months,

Reprinted from Stott and Ball, 1965.

Note Guilford's factors are listed at the left by sets of three letters. The first refers to the principal five intellectual operations: C = cognitive, M = memory, D = divergent production, N = convergent production, and E = evaluation. The second letter in each group refers to four classes of information, or content: F = figural (i.e., concrete perceived materials), S = symbolic (e.g., letters, words, digits), M = semantic content or meaning, and B = behavioral content concerned with interpersonal relations. The third letter refers to outcomes or products of the operations: U = units, C = classes, R = relations, S = systems, T = transformations, and I = implications.

Thus "CFU" refers to a factor which is described or classed as composed by cognitive, figural (perceived through senses) units. Such a factor was found at ages 3, 6, 36 and 60 months in one or more of the tests.

loadings on Memory occur for the first time. The "Other" factors in the Stott and Ball analysis are tests that would ordinarily be classed as motor coordinations. It is clear that the Cattell and the California Mental Scale do not include this type of item. [There is a separate California Infant Scale of Motor Development (Bayley, 1936), which is not included here.] Gesell included motor performance as one of the four parts of his Developmental Schedule. This factor analysis clearly separates the motor factors from the factors of intellect for the tests in which they occur.

Between 12 and 24 months there is a change in the scales used in this analysis. The Divergent Production factor does not appear in the Merrill-Palmer and Stanford-Binet, both of which were given first at 24 months. Starting with the 24-month tests, there is evidence of constricted selection of items in the areas tapped, and therefore of the factors derived. The Merrill-Palmer scale has loadings on four of the main classes with none on Divergent Production, but it also has loadings on Manual

Dexterity. The Stanford-Binet at 3, 4, and 5 years loads on Cognitive, Memory, and Evaluation factors only.

It is clear from the table that the different scales are selective, and the factors obtained are functions of the items included. The Gesell scale has a number of body-control motor factors, but only one Cognitive loading, at 12 months. Otherwise cognitive factors are well represented at all ages. It appears that memory factors cannot be tapped until 6 months or later. Stott and Ball point out that the "rational" division of tests into, for example, verbal and nonverbal tests "is not necessarily discriminative" in infancy. Profiles of types of ability may more appropriately be based on items which are grouped by appropriate factor analysis.

Although the authors do not utilize scores based on the factors they derived in order to predict later mental growth, they do present a basis for differentiating mental abilities in infancy and early childhood. In order, through use of the Guilford Structure, to explore pos-

sible continuities of related abilities across ages, it appears from this table that a wider variety of items should be selected with a view to filling as many as possible of the empty cells. Such a procedure should, theoretically, lead to a map that would show whether mental abilities grow from a simple to complex structure with age, or whether traces of the many factors of Guilford's theory can be identified in early infancy.

Another approach to identifying emergent mental abilities has been possible with the materials of the Berkeley Growth Study. Because the children in this study were tested so frequently (monthly 1 to 15 months, tri-monthly to 36 months, and biannually to 6 years), it has been possible to use as item-scores age-at-first-passing each item, for all 115 items in the California First-Year Mental Scale (Bayley, 1933b) and 110 of the items of the California Preschool Mental Scale (Jaffa, 1934). The total sample was composed of 35 males and 39 females. Through attrition, the sample was reduced over time. At 6 years 30 of each sex were tested. Inter-correlations (product-moment) using age-at-first-passing were computed between all items within each scale, and a Tryon cluster analysis was carried out for each scale. This procedure made it possible for any item on the entire scale to be included in a factor if it correlated sufficiently with the other items in that cluster. By this procedure six factors were derived for the First-Year Scale, and six for the Preschool Scale.

If a given mental ability is present throughout the first year, or over a considerable portion of the year, and if the test items are available to measure this ability, then items loading on the factor that measures it should be found over the given age-range. Actually there is no evidence in our analysis (Bayley, 1966b, Cameron, Livson, and Bayley, 1967) for such continuity in the first year. The clusters (or factors) tend to be restricted to age-levels or stages. In this regard they are congruent with the earlier interpretations of Bayley (1933a) and those of Piaget (1952).

These factors and the items loading on them at each age are shown in Fig. 4, in their ascending order of difficulty. These factors are relatively discrete. Significant correlations occur between a few which are adjacent in difficulty. These correlations are indicated at

the right in the figure. The one factor which is most clearly correlated with other factors is First-Year Factor VI, Meaningful Objective Relations. It is composed of nine items ranging in difficulty from 10 to 17 months. It correlates .34 with the adjacent Preschool Factor I, Visual Discrimination (18 to 21 months). It correlates .48 with Preschool II, Object Relations (Dexterity), 18 to 35 months, .43 with Preschool III, Memory for Form (21 to 60 months), and .42 with Preschool IV, Verbal Knowledge (Spatial), 25 to 72 months. In addition, the First-Year Factor V, Vocal Communications (8 to 14 months), correlates .45 with Preschool I, Perceptual Discrimination. The thread of relationship which runs through these five intercorrelated factors appears to be perceptual discriminations, as they are utilized in various ways: vocal-verbal and manipulatory.

From this pattern of interrelated factors whose age placements are primarily in the 10- to 60-month range, it may be suggested that in this 1- to 5-year period the child develops and consolidates his ability not only to differentiate but also to classify the objects in his experience. Both perception and language play primary roles in this process.

This kind of ability once developed, however, is not a good indicator of the later ability of these children. Instead, it may be interpreted as characterizing Piaget's stage of concrete thought processes. Such concrete processes are necessary but not sufficient conditions for the later development of abstract thinking.

The two factors, among the 12 in this series, which do correlate with later intelligence scores, are both "verbal." The First-Year Factor V, Vocalizations, is composed of items which are the beginnings of verbal communications, for example, vocalizes eagerness and displeasure, jabbles expressively, says two words. This factor, however, in the Berkeley study predicts later verbal intelligence for the girls through 26 years but for the boys only through 3 years (Bayley, 1968b, Cameron, Livson, and Bayley, 1967). The later-occurring Preschool Factor IV, Verbal Knowledge, predicts later intelligence for both sexes and, more clearly for the boys, for whom the relationship is high with later scores on verbal intelligence (Bayley, 1966b). Since language is a primary

Fig 4 Age-placement of items in the Berkeley Growth Study precocity factors for the First-Year and Preschool mental scales. Significant correlations between factor scores are indicated at the right.

tool in abstract thinking processes, we may interpret these findings as indicating that not only are verbal abilities necessary for later mental abilities, but they also play an important role in facilitating the development of increasingly abstract thought processes. If this is true, then it may be that the earlier the age at which facility in language is established, the greater the opportunity a child has to realize to the full his intellectual capacities.

In analyzing the later test scores of this same sample of Berkeley children, it was possible, for seven tests covering ages 8 to 17 years, to compute factor scores using McNemar's factors for the 1937 Stanford-Binet (McNemar, 1942). For five ages, 16 to 36 years, Wechsler adult tests were factor analyzed for this sample. In both of these scales (the Stanford-Binet and the Wechsler), the most general first factor is a verbal one, heav-

ily weighted with Information, Vocabulary, and Verbal Comprehension. The scores on these verbal factors are the most consistent over time. Further, the First-Year Vocalization factor for the girls and the Preschool

Verbal factor for the boys when correlated with the childhood and adult factors are more highly related to the verbal than to the other factors. This relation to the early Vocalization scores for the girls is illustrated in Fig 5

Fig 6 Correlations of Preschool Verbal Knowledge factor scores (24 to 72 months) with IQs at all ages (Reprinted from Bayley, 1966b)

Fig 7 Means by age and sex for Wechsler scales in Comparative Dimension A, 16 to 36 years (36-year score adjusted to equate W-B and WAIS) (Reprinted from Bayley, 1968c)

The correlation with general IQ for the Verbal Knowledge factor is shown in Fig 6

Again, these long-term stabilities of verbal scores are congruent with the conclusion that language is a consistently important tool both in the processes of abstract cognition and reasoning and in expressing the outcome of these thinking processes

A number of investigators have made use of scores which they developed from factors or clusters of correlated items, in exploring various aspects of mental organization and growth R B Cattell (Cattell, 1963), from his work on such scales, has derived a theory that intelligence is composed of two general kinds, which he calls crystallized and fluid intelligence

Cattell's theory is very relevant to questions about mental growth in adults and the age at which intelligence stops growing He and Horn (Horn and Cattell, 1966) have demonstrated clear differences in the growth curves of primary mental abilities of these two kinds of intelligence The crystallized factors are characterized by accumulated and retained knowledge, the fluid factors are processes of

discriminating and reasoning They find that crystallized intelligence continues growth for longer periods and is maintained well into old age Fluid intelligence, however, begins to decrease sometime between 18 and 38 years, the earliest losses are found in the more fluid abilities

In these studies the authors utilize cross-sectional data It is relevant to compare then findings with Bayley's (1968a) longitudinal sample for Wechsler scale scores The scores at five adult ages on the 11 Wechsler scales were analysed by the Tryon cluster method, and the clusters were then regrouped into comparative dimensions Dimension A, which is largely verbal, falls generally into Cattell's category of crystallized intelligence The scales included in Dimension A (Fig 7) are Information, Vocabulary, Picture Completion, Picture Arrangement, and Similarities All five scales showed increasing scores from 16 to 36 years, with the greater increases for the males Dimension B (Fig 8) includes the Digit Symbol substitution for both sexes and Block Design for the females only Other scales not included in either dimension are shown in

Fig 9 Most of the curves in both Figs 8 and 9 show decreasing scores for both sexes after 21 or 26 years. These six scales are similar to those classified by Cattell as fluid.

From these studies again we have evidence for multiple mental abilities, which develop in different ways. Some show more continuous growth than others. Some are more consistent over time than others. It appears that one general class of abilities, which may be referred to as verbal facility and knowledge, is not only more stable within individuals throughout growth but also continues to increase in adults to 30 years of age or older. Other abilities appear to be more bound to stages of development, to be less stable over time, and to reach their peak in the twenties. Such fluid abilities include reasoning processes, arithmetic and verbal reasoning, perhaps attention span or short-term memory, and speed.

These broad generalizations, however, leave out of account the many sex differences that become clear when the mental abilities are treated for each sex separately and when their stability over time is explored.

The evidence for continuous age changes in the nature and organization of mental abili-

ties has not been taken into account in a recent study by Bloom (1964), who has utilized published reports from longitudinal retest correlations between IQs to propose that intelligence is plastic in infancy but loses this plasticity after about 4 years of age. His theory depends on a patently inadequate definition of intelligence as a unitary mental property. However, Bloom's position that the first 4 years may be most vulnerable to the effects of extreme environments is well worth exploring. Bayley (1966c) has postulated that the important period is most likely in the second and third year, and that both environment and the changing nature of mental processes play a part in the changes occurring at this time.

DETERMINERS OF MENTAL GROWTH

These differences in various abilities and between the sexes lead us to further explorations into the nature of mental growth processes, their determiners, or at least their correlates. Differences in mental abilities have been attributed to many things, some of which may be basically hereditary, others primarily environmental, with many gradations between these extremes. The various correlates which have so far been found with mental abilities are impressive indicators of the rich complexity, still largely unexplored, of interactions among such variables as abilities, motivations, attention spans, emotional climates, environmental complexities, specific learning experiences, successes, and failures resulting from effort expended.

The Role of Heredity

Even though children's IQs are found to change over time, and these changes are often correlated with identifiable aspects of the environment, (there is also strong evidence that heredity operates to control the nature and level of mental abilities.) The best evidence for the role of heredity so far comes from two general comparisons. One is the amount of correlation between IQs of samples with differing degrees of relationship, such as parent-child, grandparent-child, siblings, cousins, twins (monozygotic and dizygotic). The other is the comparison between children reared by their own parents and children reared by unrelated, adoptive (or foster) parents.

✓ Burt, who has long been a strong proponent of heredity as the primary determiner of intelligence, recently (1966) reported an impressive analysis of his long-time studies of correlations between IQs of persons with varying degrees of familial relations and of monozygotic and dizygotic twins reared together and reared apart. His highest correlation is .92 for 95 pairs of monozygotic twins reared together. Next is the r of .87 for 53 pairs of monozygotic twins reared apart. Since such twins should be expected to have identical genetic potential, the differences between these two correlations should reflect the differential effects of growing up in different environments. His correlations of .55 for 71 like-sex and .52 for 56 opposite-sex dizygotic twin pairs reared together is very similar to the r of .53 for the 264 ordinary siblings reared together and a little more than the r of .44 of 151 pairs of siblings reared apart. He found a correlation of .27 for 136 pairs of unrelated children reared together. In other degrees of relationship he reports correlations between children and their parents as adults as .49, with parents as children .56, with grandparents .33, between uncle (or aunt) and nephew (or niece) .34, between first cousins .28, and second cousins .16. Among unrelated persons, foster parent and child correlated .27, while for children reared apart there was no relation.

Burt concludes from these correlations as well as similar ones of other investigators that hereditary factors are of paramount importance in determining mental abilities. Certainly, the role of heredity cannot be brushed aside as irrelevant, but since we do find clear patterns of correlation between measured abilities and environment, it becomes necessary, if we wish to understand the processes at work, to make more detailed examinations of these relations. For example, in Burt's studies the comparisons are not made for males and females separately, and there is evidence that environmental factors operate differently for the sexes (Bayley, 1966a). Another important variable is age. The patterns of parent-child correlations have been found to increase with the age of the child (Bayley 1954, 1966a). There is evidence also that some mental abilities are more affected than others by environments. Osborn and Gregory (1966), for example, studying 33 pairs of monozygotic

twins and 12 pairs of like-sexed dizygotic twins concluded that for some of the tests they used, as much as 89% of the within-family variance is hereditary, whereas for others the hereditary contribution was only 15%.

Another approach to the use of twins for determining the role of heredity was made by Freedman and Keller (1963) (They studied 20 pairs of like-sexed twins on a monthly basis during their first year) They selected this age because it is "before mental imitation becomes a factor." At the end of the year, by blood group determination 11 pairs were identified as fraternal and 9 as identical. On Mental and Motor scales and on the Infant Behavior Record (Bayley, 1969) within-pair differences were significantly greater for fraternal than for identical pairs. An interesting aspect of this comparison was the application of the behavior rating to filmed behaviors of the infants. Using films of 8 consecutive months of behavior of each child separately, the films of one twin were shown to a group of four professionals who had worked with children, and the films of the other twin were shown to a different, comparable group. These judges rated each child on the Infant Behavior Record, which includes such behaviors as responsiveness to persons and to toys, activity, attention span, goal directedness, fearfulness, and emotional tone. The scores for each child were then averaged. From these independent ratings intrapair differences for the fraternal twins were significantly greater ($p < .005$). From this study, there is a clear indication that personality, or nonintellective behaviors are also genetically determined. If this is so, then the correlations found at later ages between mental abilities and behaviors may result from genetically determined tendencies to react in characteristic ways to the environment. In other words, genetic determiners of mental abilities may be based not purely on capacities to carry on varying degrees of abstract thinking, but they may operate through inborn response tendencies which are manifested more generally as behaviors which in themselves are not classed as "intelligence."

Mental Abilities and Socioeconomic Background

The socioeconomic level of the children's parents has long been a subject for comparisons with children's intelligence. Figure 10

presents a series of such correlations for the Berkeley Growth Study (Bayley and Schaefer, 1964). This chart may be used to illustrate the socioeconomic variables frequently used in such correlations, as well as to give some representative correlations.

Many studies have reported correlation coefficients in the neighborhood of .50 between school-age children's IQ and parents' education and occupation (e.g., Goodenough, 1927, Kagan and Moss, 1959, Marks and Klahn, 1961). We see that for the BGS sample the relations are highest for the boys with fathers' occupation, and for the girls with both parents' education. In general, income and a social rating show only small relations. The low and even negative correlations between mental scores in infancy and parents' education were reported by Bayley in 1933. Since then similar findings have been reported by Honzik (1963), Hindley (1960), and others. An interesting aspect of the r s in Fig. 10 is that the negative correlations found with the 3- to 7-month tests occur for the boys but not for the girls. These correlations have been attributed, according to the theoretical bias of the interpreter, either to the long-term effects of environment on the child's mental development or, from a genetic basis, to the late appearance of mental abilities which are stable and similar to those evidenced by the adult parents, with a possible sex difference in the age at which the more mature, stable relation appears. There is evidence in favor of the hereditary interpretation in the study of Skodak and Skeels (1949) of parent-child relations of adopted children. In that study, as has been pointed out by Honzik (1957) the correlations between the children's IQs and those of their true mothers increase from zero at 2 years to .44 by 13.5 years, even though they had been separated from their biological mothers in early infancy. What is more, although the children's IQs were much higher than their mothers', evidently as a result of the more favorable environments afforded by their adoptive parents, there was no positive relationship found between the children's IQs and educational level of the adoptive parents.

Aside from this study of Skodak and Skeels there is little available information on children reared by other than their own parents to confirm this change with age in the true (biological) parent-child correlation in mental

Fig 10 Correlations of mental test scores by age, birth to 18 years, with five indicators of parents' socioeconomic status at the time the children were born (Reprinted from Bayley and Schaefer, 1964)

ability Bayley (1966b) has utilized the Skodak and Skeels material to compute parent-child correlations by sex of the child. As shown in Fig 11, the correlations increased with the children's ages, but for the boys the correlations at 2 years were negative (-.34 with true mothers' IQ) and then became moderately positive. The correlations for the girls rose from approximately .20 to .45 on the order of 50. The pattern holds for education of true mother and father and for IQ of true mother. The correlations with adoptive parents' education are in most instances insignificant, but with some indications of negative correlations with adoptive mothers' education.

Lesser, Fifer, and Clark (1965) have reported some relevant class and ethnic differences in school-age children for different mental abilities. An interesting aspect of this Lesser et al study is their finding that social class and cultural groups differed not only in general IQ level but also in patterns of ability. The middle-class children were consistently superior to lower-class children, with the greatest class differences in IQ for the Negroes. On Verbal Ability Jewish children scored highest, Negroes second, Chinese third, and Puerto Ricans fourth. On Reasoning, the rank order was Chinese, Jews, Negroes, and Puerto Ricans. On Number Ability, the ranks

Fig 11 Correlations of children's IQs with indicators of true parents' and adoptive parents' mental ability (data from Skodak and Skeels, 1949) (Reprinted from Bayley, 1966a)

were Jews, Chinese, Puerto Ricans, Negroes On, Space, the order was Chinese, Jews, Puerto Ricans, Negroes These findings raise the question of the extent to which the ethnic differences result from innate potentials or from differences between the groups of cultural value systems and hence of differential rewards for skills in the mental abilities tested The lower-class Negroes in this study evidently suffer the most from lack of relevant rewards for intellectual competence

Effects of Environmental Impoverishment

There is now a general consensus that children growing up in impoverished environments earn low scores on intelligence tests Among the most impoverished environments to which many young children have been subjected are the orphanages and other institutions in which infants and young children are cared for over protracted periods The mental and emotional deprivations of such children have been reported in the well-known studies of Spitz (1945), Goldfarb (1945, 1955), Bowlby (1952), and others The effects of an orphanage environment can perhaps be best illustrated in a pioneer study

at the University of Iowa (Skeels, Updegraff, Wellman, and Williams, 1938) The children were retarded in mental, motor, and social maturity A significant finding of this study is that a small group of these children who were given training in an enriched preschool program showed marked gains in all three areas These gains resulted, at least in part, from the children's learning of skills in interacting with adults, and in attending and responding in a relevant way to stimuli which would facilitate adequate measures of intelligence However, this process of meaningful interaction would in itself promote mental growth, if this is true, then Skeels and his associates are correct in their assertion that the children's intelligence actually increased as a result of their preschool experience

The Effects of Physical Impoverishment

On the physical side, low socioeconomic status and economically deprived populations are regularly associated with poor nutrition, high incidence of disease, slow growth, and small size Along with these conditions, we also find diminished mental ability It is dif-

difficult to differentiate the effects of these physical hazards from the environmental aspects of impoverishment discussed previously. However, there is some evidence that poor health and nutrition in themselves contribute to lowered mental abilities.

It seems reasonable that children with poor health or inadequate food will lack the energy, drive, and curiosity for the sustained attention and effort required for solving difficult problems or carrying through to completion complex, logical thought-processes. However, such generalizations may not be adequate to explain the deficits. There is recently an increasing body of evidence from animal studies which indicates that dietary deficiencies, specifically of protein, may actually impair nervous tissues.

Perhaps the most definitive of these studies to date is by Zamenhof, Maithens, and Margolis (1968). They fed controlled diets to young female rats, starting 1 month before pregnancy and continuing throughout gestation. The only differences in the diets were that one group was fed a low protein and the other a high protein diet. The brains of the newborn rats were analyzed. DNA and protein were determined for the litters of the rats on the two differing diets. The results showed significant differences between the dietary groups not only in body and brain weights, but the progeny of the protein-deprived mothers showed a significant reduction in the total number of brain cells. In addition, the amount of protein per cell was lower. Therefore, the authors conclude that "This quantitative alteration in number as well as the qualitative one (protein per cell) may constitute a basis for the frequently reported impaired behavior of the offspring from protein-deprived mothers."

The results of this and similar studies on animals may be compared with a study by Stoch and Smythe (1963) on two groups of Cape colored children in South Africa. One group had been severely malnourished in the first year of life, the other adequately nourished. At the end of 7 years, the malnourished group was significantly below the other in stature, IQ, and head circumference. It was pointed out that the age at which nutritional deprivation occurred in these children was at a crucial stage for brain development. During the first year the brain is still growing rapidly

and is still in the process of myelination. Several more carefully designed studies on young children are now in process, and eventually it should be possible to know whether and to what extent early protein deficiency in the diet has a directly depressing effect on intelligence.

Several forms of mental retardation are now known to result from genetic anomalies that interfere with normal development. Among these are cretinism (congenital hypothyroidism implying subnormal secretion of thyroxine), phenylketonuria (an inborn "error" of metabolism which results in, among other things, a greatly reduced capacity to convert phenylalanine to tyrosine), and mongolism (or Down's Syndrome), whose cause beyond the evidence of a characteristic chromosome pattern has not been completely determined (Penrose and Smith, 1966). With time and better techniques, it may be possible to identify most of the specific determiners of mental retardation. As this process continues and the hereditary and environmental determiners of mental defects become known, corrective measures for each may become possible.

Effects of Intervention on Mental Abilities ✕

Psychologists and educators were slow to accept the implications of the Iowa studies on the effects of inappropriate living conditions because at that time the concept of the "constant IQ" was thoroughly ingrained in the theoretical formulations about the nature of intelligence. In recent years, with the accumulation of evidence that children's IQs do change, and that these changes often appear to result from environmental conditions, numerous studies designed to assess the effects on mental abilities of various types of interventions have been reported. These interventions may be concerned with improving motivation, or supplying opportunities to learn, or reducing anxiety, or eliminating debilitating diseases and malnutrition.

A good example of an experiment to increase mental abilities in young children is the one at Peabody College, in which the aim is to control the environment through appropriate reinforcements. Gay and Klaus (1965) made an interim report at the end of the third year of this 5-year project to improve the mental abilities of culturally deprived Negro children. From an analysis of the general en-

environments of these children they selected five most probably relevant dimensions of patterns of interaction between the children and adults. These dimensions are (1) total amount of reinforcement of the child's behaviors, (2) the source of reinforcement, (3) the amount of verbal reinforcement, (4) the direction of reinforcement, and (5) the focus of the reinforcement. That is, (1) the culturally deprived mother spends her time *coping with*, rather than *shaping* her child's behavior, (2) those reinforcements the child gets are most often from siblings and peers, (3) very little of the reinforcement is verbal, (4) it is directed toward keeping the child quiet and easy to manage and thus discourages spontaneity and curiosity, and (5) it is vague and general ("you're a bad boy") rather than relevant to specific behaviors.

In a research design involving 87 children, divided into two experimental and two control groups, starting at 3 years all children were given mental tests twice a year for 3 years, with plans for two additional annual follow-up tests. One experimental group was given special nursery school training for 3 summers, the second experimental group, starting at 4 years, had 2 summer school training sessions. In the original tests the average Stanford-Binet IQ of the experimental groups was 88, that of the control groups was 86. At the end of the third year the experimental groups' IQs averaged 95, whereas the control groups' IQs had dropped to 81. The difference is significant at the .05 level of confidence, or better. Similar differences were obtained for the Peabody Picture Vocabulary Test (Dunn, 1959) and the Illinois Test of Psycholinguistic Abilities (McCarthy and Kirk, 1961-1963).

Recently an enrichment program for institutionalized mongoloids (Bayley, 1966c, Bayley, Rhodes, and Gooch, 1966) has shown that intensive training with emphasis on language can increase the mental scores of 4- to 6-year-old mongoloids to levels more in line with the performances of a home-reared matched control sample.

Such increases, as exemplified in the preceding and other studies, at least have the practical effect of increasing the level of the children's mental functioning at the time. A further question that may be asked here is the extent to which the beneficial effect of

these training experiments is maintained as the children grow older. Skeels (1966) has shown that the benefits do last for a small sample of 13 institutionalized Iowa children who were mentally retarded as infants. These babies were given enriched experiences that involved individualized love and attention from adult mother-surrogates, and all but two were later placed in adoptive homes. The mean IQ of these children at 18 months when the study started was 64, and on the latest testing at 6 years, their mean IQ was 96, a gain of 30 points. A contrast group from the orphanage had a mean IQ of 87 at 17 months and of 66 at 7 years, a loss of 21 points. In his follow-up study of these two groups as adults Skeels found striking differences between them. For example, the experimental group had a median of twelfth-grade education, the contrast group of third grade. Eleven of the experimental group were married, nine of them had children, only two men of the control group had married, and one had one child. Those in the experimental group were self-supporting or functioning well as housewives, those in the contrast group were either inmates of an institution or unskilled laborers. On the Warner scale of socioeconomic status the experimental group fell in the lower-middle-class category, the contrast group in the lower-lower class. Clearly, the early gains of the experimental group had been maintained.

The extent to which such environments are impoverished in a meaningful way is to some degree a function of the child's stage of mental development. Rheingold (1956) has shown that the enrichment provided by the one-person mothering of 6- to 8-month-old institutionalized infants did not show increased mental growth, although it did increase the baby's social responsiveness. A follow-up on these children a year later (Rheingold and Bayley, 1959) showed no differences between the experimental (mothered) babies in either IQ or social responsiveness, although the mothered babies were perhaps a little more talkative. If these findings are related to the information from the factor analyses of mental organization in the first year, we may tentatively assume that a rather simple bland environment is not depriving until the children are about 8 to 10 months old, and capable of perceptual discriminations in which meaningful relationships among objects and events are

recognized, and incipient language communication is present

The Role of Emotions, Attitudes, and Drives

In recent years there is increasing evidence from several longitudinal studies for the role of the emotional climate in children's mental growth. Moss and Kagan (1958) have found moderate correlations between the children's IQs at 3 years and maternal concern with the child's achievement

Hill and Sarason (1966) report the effects of test anxiety and defensiveness on abilities in a longitudinal study of school children. In this study increasing anxiety was related to decreasing test performance in one group of children from the first to fifth grade. For another group from fourth to sixth grades, increases in anxiety were also accompanied by lower test scores but more significantly in the boys than in the girls. As Hill and Sarason point out, during the intervals between tests "the child is faced with a number of new, important and varied tasks of a cognitive and interpersonal nature" Anxiety decreases as a child masters the problems he faces and increases as he finds new problems that he does not know how to cope with. The result appears to be an interaction between degree of anxiety and test scores. On the one hand, relief from anxiety comes from successful performance. On the other hand, severe anxiety over new difficulties may interfere with a child's full use of those abilities he does have, in his efforts to find good solutions to these new problems.

Honzik, Macfarlane, and Allen (1948), in a study of mental test performance from 2 to 18 years, show that a number of the children who experienced emotional disturbances during this period of growth maintained relatively stable IQs. On the other hand, where there were instances of marked instability, the fluctuations in IQ paralleled fluctuations in the emotional climate in the home.

One example they give indicates this kind of fluctuation in a boy whose scores were affected by the emotional climate of the home. When first tested at 21 months, his IQ was 106, he was very shy, and the mother, who was uneasy, had been subjected to periods of acute anxiety. This same child, however, at 4 years had an IQ of 140, he was less shy, and the family situation was much improved, the

mother reporting this as the best period in her marriage. At 6 years, when the mother was again acutely disturbed, the child's IQ dropped to 123. After this his test scores gradually rose as the home situation improved until at 12 years his IQ was 163. Two years later, with a recurrence of the mother's mental disturbance, the boy's IQ started dropping, and at the 18-year test, when he was depressed and worried about his heredity, his IQ had fallen further, to 122.

Another approach to the parent-child relations was made by Bayley and Schaefer (1964) for the same Berkeley Growth Study for which the correlates of socioeconomic status are presented in Fig 10. Ratings of the mother's behavior were made from observational notes written during the testing sessions in the children's first 3 years. A second set of ratings was made from an interview with the mother about 10 years later. Both sets of these ratings may be classed, roughly, into behaviors that are warm, understanding, and loving, as opposed to punitive and harsh, and those that grant autonomy and freedom in contrast to those that are controlling and intrusive.

When the maternal behaviors are arranged in an order of neighboring, based on their intercorrelations, from autonomy through love, control, and hostility, to ignoring, the pattern of their correlations with the children's intelligence scores shows consistent shifts both with age and by sex. These patterns of relation to the early (0 to 3 years) maternal behaviors are illustrated in Fig 12, 13, and 14. Figure 12 presents, for each sex, the correlations of the maternal behaviors with test scores in the first year. Each bar represents the average of three consecutive tests. There are four of these three-test averages for the first year, and each maternal behavior is correlated with the four levels. In the first year the boy's scores are seen to be negatively correlated with equalitarian, affectionate maternal behaviors but positively correlated with maternal hostile rejecting behaviors. For the girls these correlations are reversed. For both sexes controlling, achievement-demanding maternal behaviors are positively correlated with children's scores. As the children grow older, the pattern shifts. At the preschool ages, shown in Fig 13, the boys' correlations become more like those for the girls. At school ages (Fig 14)

Fig 12 Correlations between maternal behavior (0 to 3 years) and intelligence at four age-levels, 1 to 12 months (Reprinted from Bayley and Schaefer, 1964)

the boys' scores are seen to be clearly related to the early maternal love-hostility dimension, whereas the girls' scores are almost completely independent of these maternal variables. For the boys there is a correlational pattern which may be stated briefly: early maternal love and acceptance goes with slow development at first but later high achievement in mental abilities, with the reverse pattern for boys with punitive rejecting mothers. For the girls, although early maternal love goes with high scores in infancy, its influence diminishes after 3 years and then drops out almost completely.

The later maternal behaviors, when the children's ages were 9 to 13 years, were found to be related to their sons' intelligence in

much the same way as were their early behaviors. In contrast, the girls' test scores show little or no relation to their mother's attitudes toward them as preteen-agers. In general it appears that the relatively stable maternal behaviors (which have been classified as love or warmth versus hostility or rejection) were continuously related to the boys' abilities, while the girls' abilities after 3 or 4 years remained relatively free of their mothers' behaviors.

These findings are in many ways in agreement with those from another, similar population, the Berkeley Guidance Study, as recently reported by Honzik. She investigated parent-child relationships of children's intelligence and several aspects of the family en-

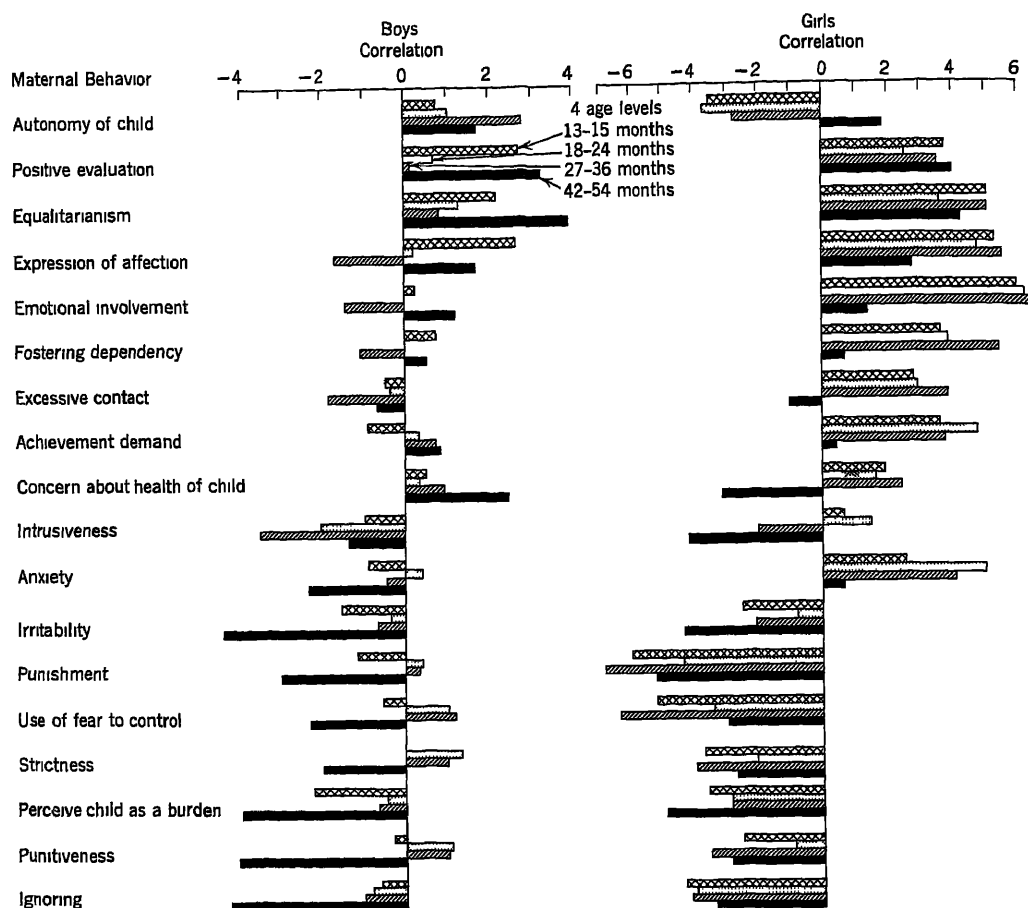

Fig 13 Correlations between maternal behavior (0 to 3 years) and intelligence at four age-levels, 13 to 54 months (Reprinted from Bayley and Schaefer, 1964)

vironment as observed over time, starting when the children were 21 months old. The parental variables were correlated with children's IQs between 21 months and 18 years (1967a) and with their scores on the Wechsler-Bellevue subscales at 18 years (1967b). The importance of this longitudinal study is accentuated by the fact that there is considerable information about the fathers as well as about the mothers. The sample size at each test age varied around 55 for each sex, with a range from 39 to 59 for ages 2 to 18 years. Honzik found that for tests at ages 6 to 18 years there were consistent sex differences in the correlations with IQ. The sons' IQs correlated more highly "with a rating of close mother-son relation and with the father's occupational success and satisfaction." The daughters' IQs were positively correlated with

"father's friendliness to this daughter" and with ratings of parental compatibility. Scores of both sexes correlated positively with parents' concern for their achievement (Honzik, 1967a).

The correlations with the 18-year W-B subscale scores (Honzik, 1967b) are based on a sample of 41 boys and 40 girls. For this sample, findings on the relation between early maternal affection and children's 18-year IQs is very similar to the Bayley and Schaefer (1964) results for similar ages. Boys' Verbal IQs correlated with maternal behaviors described as "close" .56, as "friendly" .34, and as "affectionate" .27. For the "close" and "friendly" variables the mother-daughter correlations were each .29. The highest mother-daughter r was with maternal "concern about health" (.42). The girls' W-B Performance IQ

was positively correlated with mothers' irritability. In contrast, the girls' but not the boys' 18-year scores, were correlated with a close affectional relationship between the father and the mother. The parent-child correlations of the early affectional relationships to the subscale scores of the 18-year Wechsler-Bellevue tests are shown in Fig. 15.

In the Berkeley Growth Study, the children's own behaviors, as rated during the tests, were seen to be related to their mental scores (Bayley and Schaefer, 1964). These relations may be summed briefly as follows:

Boy babies who were rated as happy, positively responding, and calm tended to have low scores in the first year or so and high scores by 4 or 5 years and later. If they were active between 10 and 15 months, their scores were high early but low after 4 years, if they were active after 15 months, the pattern of mental scores was reversed, that is, active 2-year-old boys tended to have high IQs at later ages. As for the girls, happy, positive, and calm behaviors correlated with high mental scores early, but the correlations approached zero after 3 or 4 years.

Fig. 14 Correlations between maternal behavior (0 to 3 years) and intelligence at five age-levels, 5 to 18 years (Reprinted from Bayley and Schaefer, 1964)

Fig 15 Correlations between parental behaviors and 18-year IQ in the Berkeley Guidance Study
(Reprinted from Honzik, 1967)

Series of ratings during childhood showed for both sexes significant correlations between IQ and friendliness, cooperativeness, attentiveness, and facility, although for the girls the correlations were high primarily for concurrent ages at test and rating. At adolescence, the boys with high mental ability were rated as friendly, social, and independent, low-scoring boys as reserved. There were no significant relations between the adolescent girls' behaviors and their IQs.

In two recent studies Bayley (1968a, 1968b) reports relations between personality variables and test scores for these same subjects through 36 years for a total of 54 cases. In these studies the subscores representing different mental ability "factors" and subscores have been compared with two sets of adult personality variables in addition to the earlier behavior ratings.

It has been possible to obtain scores of

verbal ability from the tests at most ages, starting with the First-Year Vocalization (8- to 14-month) precocity score. These verbal scores, for this sample, appear to be the most stable as well as the most saturated with g (general intelligence) of the factors derived. It is interesting therefore to relate verbal scores through 36 years to the early ratings of infant behavior. These patterns of correlation are shown in Fig 16, 17, 18, 19, and 20. In Fig 16 and 17 we see that the boys who were active and rapid through 15 months tend to make low scores through 36 years, whereas similar ratings after 15 months go with persistently high later scores. Figures 18 and 19 show the long-range persistence for boys, but not for girls, of positive and happy behaviors as indicators of above-average verbal ability. In Fig 20 we find some indication that girl but not boy babies, who were shy before 2 years are among those who later

Fig 16 Correlations between ratings of Activity at ages 10 to 36 months and Verbal scores for all ages 1 to 36 (Reprinted from Bayley, 1968b)

Fig. 17 Correlations between ratings of Rapidity at ages 10 to 36 months and Verbal scores for all ages 1 to 36 years (Reprinted from Bayley, 1968b)

Fig 18 Correlations between ratings of Positive Behavior at ages 10 to 36 months and Verbal scores for all ages 1 to 36 years (Reprinted from Bayley, 1968b)

Fig 19 Correlations between ratings of Happiness at ages 10 to 36 months and Verbal scores for all ages 1 to 36 years (Reprinted from Bayley, 1968b)

Fig 20 Correlations between ratings of Shyness at ages 10 to 36 months and Verbal scores for all ages 1 to 36 years (Reprinted from Bayley, 1968b)

score high in verbal ability. In general, the scores after 4 years show very different relations to these infant behaviors than do the scores earned at the time.

Another aspect of the relations between mental abilities and attitudes and interests is revealed in the correlations with the Wechsler scale scores at 16 to 36 years. These have been correlated with scores on sets of 70 behaviors based on Q-sorts (with the Block Q set, Block, 1961). The behaviors have been arranged in a Guttman (1954) order of neighboring, or circumplex. The circumplex arrangement places a set of variables in a circular order in such a way that highly intercorrelated items are close together, uncorrelated items are about 90° apart on the circle, and negatively correlated items are on opposite sides of the circle, with the strongest negative correlation 180° apart.

Examples of related behaviors with their angular placements on the circumplex for the males in this sample are such uncontrolled or expressive behaviors as 18° Expresses hostile feelings directly, 33° Represses anxiety and conflicts, 46° Is self-indulgent, 58° Unable to delay gratification, 69° Irritable, 72° Transfers blame to others. Withdrawn be-

haviors include 110° Vulnerable to threats, 121° Submissive, 126° Keeps people at a distance, 144° Avoids action. Generally intellectual behaviors are 232° Socially perceptive, 236° Values intellectual matters, 244° Wide range of interests, 246° High intellectual capacity, 252° Sees to heart of important problems. Expressive adjusted or gregarious behaviors are 273° Has warmth and capacity for close relationships, 277° Objective, 278° Calm and relaxed, 280° Good-looking, 285° Gets things done, 288° Liked and accepted by others, 312° Satisfied with self.

The circumplex for females is similar to the males', except that the maladjusted half of the circle is better described by the terms conventional and negative. The conventional quadrant includes such items as 11° Fastidious, 16° Conservative, 34° Conventional, 37° Moralistic, 49° Transfers blame to others, 63° Bland. The negative quadrant includes 99° Self-pitying, 102° Subtly negativistic, 109° Persistent and preoccupying thoughts, 111° Irritable, 111° Hostile, 116° Moody, 136° Changeable. The Intellectual and Gregarious behaviors on the adjusted half of the circle are very similar to those of the males.

With this organization of the ratings of

Fig 21 Circumplex-ordered correlations between 36-year Block Q-set scores and WAIS Verbal and Performance IQs at 36 years for males (Reprinted from Bayley, 1968b)

patterns of behaviors, it is possible to compare the relations between behavior tendencies (or personalities) and mental abilities. The pattern of correlations with the Verbal and Performance WAIS scores at 36 years is shown for the males in Fig 21 and for the females in Fig 22. The correlations for both parts of the test are high with behaviors which are characterized as introspective-adjusted, that is, High intellectual capacity, Wide interest, Thoughtful, and Fluent, whereas strong negative correlations are found with maladjusted expressive behaviors such as Uncontrolled, Expresses hostile feelings freely, Impatient. The correlations show greater extremes with the verbal than with the nonverbal scale. The correlational pattern for the females (Fig 22), although it tends to follow the same directions of positive and negative correlations, is much less marked. Other comparisons show that the pattern for the males is as strong with the 16-year Wechsler-Bellevue tests as with that shown in Fig 21 for 36 years. However, for the

females the relations across time drop out. There are evidences also, for each sex, of somewhat different patterns of correlations between the Q-sort variables and the different subscales of the Wechsler tests. The pattern of correlations is even reversed in the 16-year Information and Arithmetic scales. For example, at 16 years the girls' correlation between scores on Arithmetic and "Warmth" is -42 and with "Charm" is -62 , positive correlations are found between Arithmetic and "Feels a lack of personal meaning in life" (48) and "Is subtly negativistic" (64).

In another study (Bayley, 1968a) these same Wechsler scores have been correlated with the 18 behaviors of the California Psychological Inventory (Gough, 1957), a self-rating instrument. In this study, again, there are patterns of positive and negative correlations with test scores, and marked sex differences. The sexes are most alike in their relations to verbal scores (Fig 23), whereas the greatest differences are for Digit Span (Fig 24).

It is evident that the behavioral and emotional correlates of mental abilities are complex, and there is need to explore these differences more thoroughly. From much of the evidence discussed here, there are clear indications that mental abilities of males are more strongly related than the females, both positively and negatively, to emotional aspects of their environment. There are also indications that for the boys, early experiences are likely to have long-lasting effects, even though the nature of these effects may not at first be evident.

SUMMARY

In following the processes of mental growth from birth to some time near 30 years, when growth in most mental test scores finally appears to level off, it becomes clear that mental abilities are complex both in their nature and in their causes. With growth, abilities change in nature as they become increasingly complex and as they move from concrete to abstract processes. Abilities which are characteristic of a given stage of develop-

ment may or may not be predictive of later mental capacities.

In general, mental test scores indicate variable rates of growth in the first 3 or 4 years, but become more stable after that age.

The most stable of the mental abilities which have been differentiated appear to be verbal in nature. Verbal scores stabilize earlier in girls. However, once established, the boys' verbal scores may be more consistent than the girls'.

There is some evidence that during growth mental abilities in females are more independent of emotional climates than is true for males. There are also some indications that for the males early emotional conditions may be more persistent in their effects on later mental growth.

Such characteristics as degrees of drive, perseverance, and attention span, which themselves are in varying degrees genetically determined, may operate to enhance or retard the development of mental abilities.

The complex interaction of genetic potentials and environmental stimulation, in the

Fig 22 Circumplex-ordered correlations between 36-year Block Q-set scores and WAIS Verbal and Performance IQs at 36 years for females (Reprinted from Bayley, 1968b)

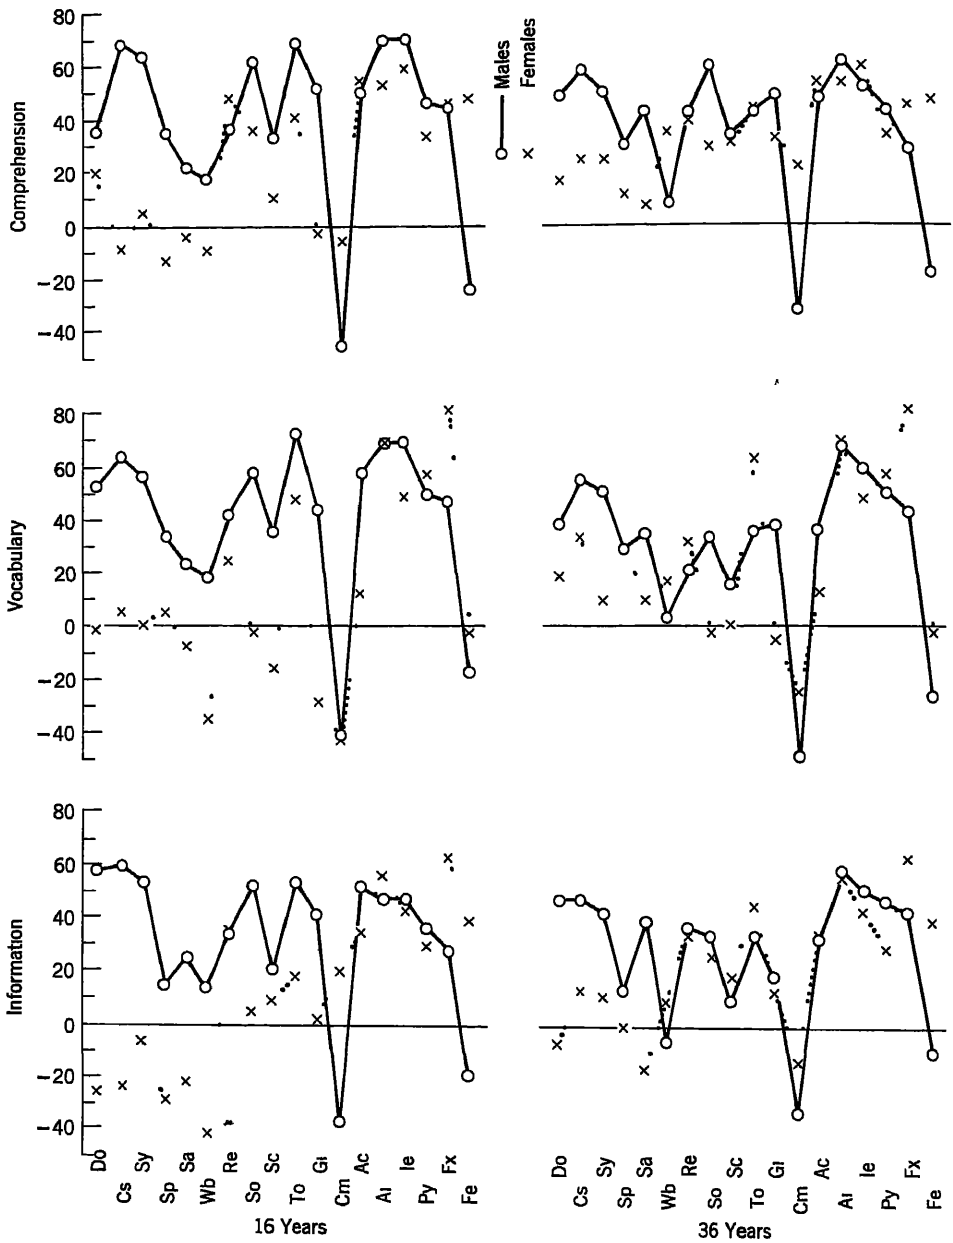

Fig 23 Correlations by sex between California Psychological Inventory at 36 years and Wechsler Information, Vocabulary, and Comprehension scores at 16 and 36 years (Reprinted from Bayley, 1968c) Key Do = dominance, Cs = capacity for status, Sy = sociability, Sp = social presence, Sa = self-acceptance, Wb = sense of well-being, Re = responsibility, So = socialization, Sc = self-control, To = tolerance, Gi = good impression, Cm = communality, Ac = achievement via conformance, Ai = achievement via independence, Ie = intellectual efficiency, Py = psychological-mindedness, Fx = flexibility, Fe = femininity

context of maturing and pliable neural structures, presents a setting in which the exact expression of mental abilities may be impossible to predict. However, we have in this complex process a number of indicators of the best ways to facilitate mental growth.

In essence, given the undamaged genetic potential, mental growth is best facilitated by a supportive, "warm" emotional climate, together with ample opportunities for the positive reinforcement of specific cognitive efforts and successes.

17. Creativity

MICHAEL A WALLACH

There is no end to the study of creativity, and almost no beginning. Perhaps especially in our culture, with its abiding value emphasis upon excellence or competence by some criterion or another, it is not surprising that a term which can epitomize virtually whatever the society values in its members should be so widely celebrated. There is, however, a danger in this practice: what is called creativity today may simply describe what was called by some other name in the same culture only yesterday. One need not go back too far in time within the circles of child psychology and education to find other terms with denotations suspiciously similar to what is called "creativity" today—such terms as giftedness, insight, discovery, intuition, and, indeed, intelligence.

The range of emphases that can be embraced by the creativity term has been indicated and documented at length in a number of recent reviews (e.g., Stein and Henze, 1960, Getzels and Jackson, 1962, Barron, 1963, Golann, 1963, Taylor and Barron, 1963, Taylor, 1964a, 1964b, Barron, 1965, and Taylor and Williams, 1966). Faced with such a profusion of material, and especially in a chapter that must take as its frame of reference the study of children, adolescents, and young adults, certain limitations must be imposed upon the task one seeks to accomplish. These limitations of focus will be set forth in this introductory section.

A rough distinction can be made in the creativity literature among studies oriented to products, to persons, and to processes. The first two of these three perspectives have in the nature of the case taken the examination of mature adults as their point of departure.

Thus, for example, an extensive literature has accumulated concerning evaluations of the products of research scientists. The bases for evaluation of products have been varied, including such indices as occupational salary, number of publications, membership in various professional organizations, listing in such sources as *Who's Who in America*, output of patentable inventions, and ratings by peers, supervisors, or panels of informed judges (see, e.g., Knapp and Goodrich, 1952, Taylor, 1959, Taylor, Smith, Ghiselin, and Ellison, 1961, Harmon, 1963, Taylor, 1963, Taylor, Smith, and Ghiselin, 1963, Chambers, 1964, Hoyt, 1965, and Taylor and Ellison, 1967). A provocative conclusion has emerged from some of this work: the worth of scientific contributions seems to be relatively independent of traditional intellectual assessment information available as of the college years. Other studies in this field, on the other hand, have found relationships with customary intellectual data. Product-centered criteria of these various kinds, however, turn out to be relatively uncorrelated among themselves (e.g., Golann, 1963), so that it is difficult to justify the application of some single term such as creativity to all of them. Furthermore, here one is considering primarily the occupational achievements of mature adults—a task that would easily require a chapter in its own right.

A second perspective in the creativity literature has been concerned with describing the personalities of individuals who have been judged creative by virtue of evaluations of their occupational products. Although, to be sure, this line of endeavor overlaps with the first, a difference can be delineated in terms

of the degree to which the investigator seems more concerned with studying products as criteria of creativity or with studying the persons who become identified through any means as creative. The emphasis has been upon painting a picture of what the person who achieves eminence in the arts or the sciences is like (see, e.g., Roe, 1951a, 1951b, 1953a, 1953b, Cattell and Drevdahl, 1955, Drevdahl and Cattell, 1958, MacKinnon, 1960, 1962a, 1962b). Given, for example, the identification of some architects as more creative than others in terms of the judgments of fellow architects who are recognized as competent to make the evaluations, MacKinnon (1960, 1962a, 1962b) has been interested in depicting, through the use of a wide range of measurement probes, what the creative architect is like. Not surprisingly, he turns out to be a very complicated person. "The successful and effective architect must, with the skill of a juggler, combine, reconcile, and exercise the diverse skills of businessman, lawyer, artist, engineer, and advertising man, as well as those of author and journalist, psychiatrist, educator, and psychologist" (MacKinnon, 1962b, p. 486). Work that is focused upon creative persons requires essentially comments similar to those we offered concerning work that is focused upon creative products. There is, of course, a great variety of relatively disjunctive ways in which the term creativity is applied, yet we find again that the major focus is upon the occupational achievements of mature adults. Thus the literature concerned with creative persons turns out once more to be a vast one that would easily constitute the subject matter for yet another chapter.

We turn, then, to the third perspective that has concerned students of creativity—processes. It is this perspective upon which we propose to concentrate in the present chapter, for it is on processes that research presuming to study creativity in children, adolescents, and young adults has concentrated. To propose that there are in fact psychological processes that can be appropriately assigned to the creativity concept is to argue that these processes cannot be embraced within the ways that are already at hand for understanding thinking, that these processes have some face validity for being described in terms of a disposition for creativity, and that these

processes are necessary, although they need not be sufficient, for the achievement of products that the society would construe as reflecting creativity. Most of the research conducted thus far has dealt with the first two of these points, and hence these are the issues that will mainly concern us. Research is sorely needed concerning the third—an imbalance that hopefully will be redressed by the time the next edition of this book appears.

The early history of the concern with thinking processes that are involved in creativity (e.g., Wallas, 1926, Woodworth and Schlosberg, 1954) tended to make use of concepts drawn from the study of problem-solving. Whether the use of models drawn from general problem-solving can succeed in describing thinking processes that differ from the more mundane ones, which we would not want to call creative, however, is a moot point, and one that will be of continuing concern to us. If problem-solving skill is all that the term creativity can mean at the level of psychological processes, use of the term will gain us nothing. The concept of general intelligence has, after all, been with us for a long time as a descriptive summary for the abilities that contribute to effective problem-solving, and these abilities have been found to cohere in the sense that individuals can be reliably ordered in terms of their overall competence at coping with the problems offered them by their environment. Indeed, the intelligence concept forms the focus of another chapter in this *Manual* (see chapter by Bayley). Are there thinking processes, then, that differ from those that form the basis for the general intelligence concept, and that at the same time possess face validity as signs of creativity? To suggest such processes differ from those associated with intelligence is to ask whether a dimension of individual differences can be located whose content reflects processes that seem appropriately described as a disposition for creativity or as a creative ability trait, but which is still essentially independent of individual differences in general intelligence.

THE INITIAL STIMULUS

Guilford and the Structure-of-Intellect Model

Theoretical Considerations. The major impetus to the search for thinking processes that

may be appropriately described as concerned with creativity dates from the work of J. P. Guilford and his associates beginning in the early 1950s. For the last 15 years or so, they have been seeking to evaluate a model of how humans think that involves three basic considerations: processes or thinking operations carried out, contents to which the operations are applied, and products that can result (e.g., Guilford, 1956, 1957, 1959a, 1959b, 1959c, 1963, 1964, 1967a, 1967b). The kinds of process Guilford calls attention to may be roughly grouped into those concerned with raw informational material, those concerned with producing further information from what is already in hand, and the process of making evaluations concerning information that confronts us. Regarding raw material, Guilford distinguishes between *cognition*—the perceiving of data from the outside world—and *memory*—the retention of what has been perceived. Regarding the producing of further information, he distinguishes between *convergent* thinking—zeroing in upon an answer that is rather precisely implied or specified by the nature of the informational givens—and *divergent* thinking—searching for material that is only loosely related to what is already known, so that one's search model has a much more broad-gauged template than in the former case. The fifth process to which Guilford calls attention, *evaluation*, refers in turn to whatever is involved in reaching decisions about the appropriateness, suitability, elegance, or goodness of material that is perceived, remembered, reached by convergent thinking, or reached by divergent thinking.

The further major considerations involved in Guilford's structure-of-intellect model are descriptive in character. They concern possible distinctions that can be drawn among contents to which the forgoing processes can be applied—such as meaningful verbal content, numbers, or material that represents nothing beyond itself, and possible distinctions among the products that can eventuate from applying the processes to one or another kind of content—such as logical arrangements of classification or implication. Our attention quickly returns, therefore, to the cognitive operations that he postulates and, among these, to the concepts of convergent and divergent thinking in particular. Some kind of evaluative process, after all, is implicit in

carrying out any kind of cognitive work, and such work must in the nature of the case begin with the raw materials supplied by the senses and memory. The core of Guilford's analysis of the processes by which thinking is carried out thus consists of his distinguishing between convergent and divergent cognitive operations.

In view of the active nature of creative performances, the production aspects or steps are most conspicuous and probably most crucial. Among the productive-thinking abilities another logical distinction appears. With some productive-thinking factors and the tests that measure them, thinking must at some time converge toward one right answer; the significant type of thinking involved has been called "convergent thinking." With other productive-thinking factors and their tests, thinking need not come out with a unique answer, in fact, going off in different directions contributes to a better score in such tests. This type of thinking and these factors come under the heading of "divergent" thinking. It is in divergent thinking that we find the most obvious indications of creativity (Guilford, 1957, pp. 111–112).

In order further to characterize what Guilford means by divergent thinking, let us turn to the specific divergent-thinking subprocesses that the Guilford group claims to have isolated by factor-analytic techniques, and briefly describe each (see, e.g., Wilson, Guilford, Christensen, and Lewis, 1954; Guilford, 1956, 1959a, 1959b). They are "word fluency," "associational fluency," "ideational fluency," "expressional fluency," "spontaneous flexibility," "adaptive flexibility," "redefinition," and "originality."

Word fluency refers to the ability to generate words that fulfill particular structural requirements, such as providing as many words as possible that begin with a certain letter or solving anagrams.

Associational fluency refers to the ability to rapidly generate words that meet particular requirements of meaning, such as providing a word which has the same meaning as each of a pair of words that differ in meaning themselves.

Ideational fluency refers to the ability to generate—within a limited time—ideas that

will fulfill particular requirements, such as naming uses for bricks, naming problems that are suggested by certain common situations, writing titles for a story plot, or naming the consequences that might be entailed by certain changes

Expressional fluency concerns the ability to put rapidly into juxtaposition words that meet particular requirements of sentence structure, such as writing alternative four-word sentences when the first letter of each word in the sentence is specified

Spontaneous flexibility denotes the ability to vary one's ideas over a wide range, even though this is not specifically called for on the test, such as giving many different categories of possible uses for a brick rather than offering uses that all fall within the same general category

Adaptive flexibility refers to the ability to vary one's ideas widely when the test requires such variety be displayed, for example, solving problems wherein a given number of matchsticks must be removed from a particular array of matchstick triangles in such a way that a certain number of triangles will remain

Redefinition concerns the ability to relinquish old ways of construing familiar objects in order to make use of them for a new purpose, such as choosing from among five objects one with a part that will serve some function alien to the customary usages of all the objects (called "Gestalt Transformations")

Originality, finally, refers to the making of responses that are statistically unique or unusual, such as the giving of uncommon uses for a brick, the hypothesizing of nonobvious consequences as ones that might follow from a particular event, or the offering of plot titles that are evaluated as clever

In sum, then, four of these divergent-thinking factors concern some form of fluency, three of them concern some sort of flexibility, and one involves novelty or uniqueness. Convergent thinking, on the other hand, refers to tests that probe such matters as verbal comprehension, verbal reasoning, the size of a person's vocabulary, and the ability to solve mathematics problems. It is evident that such procedures assess what is commonly referred to as the general intelligence concept. Here too, the Guilford group argues that a large number of specific subprocesses are disclosed

by the results of factor analysis. Before turning to the evidence that bears upon the tenability of the Guilford group's distinction between divergent- and convergent-thinking processes, however, several further points require consideration—two issues concerning the face validity of the creativity indicators and one concerning the relationships among individual differences in performance on the various tasks that we have described.

Despite the fact that the Guilford group defines divergent thinking in terms that oppose a search for particular correct answers, they have, as Wallach and Kogan (1965a) point out, embedded their divergent-thinking tasks within an evaluative testing context—hence one that is familiar to the respondents as putting a premium upon the locating of right answers. By the Guilford group's own definition of divergent thinking as thinking which "goes off in different directions," therefore, an ability-testing context with its natural emphasis upon correctness may not be maximally conducive to divergent thinking's display.

In addition to its reliance upon a context of ability testing and partly as a result of this reliance, the Guilford group also has imposed time limits—usually quite stringent ones—upon its divergent-thinking tasks (Wallach and Kogan, 1965a). Again returning to Guilford's own definition of divergent thinking, however, there would seem to be no reason to put a premium upon speed of responding. Rather, the concept of thinking in different directions suggests an emphasis upon freedom and spontaneity that is quite inconsistent with the imposition of brief time limits upon performance. The face validity of the divergent-thinking tasks hence would seem greater were they administered without time limits and in a context that did not carry ability-testing connotations.

Can assessors of divergent and convergent thinking be distinguished in terms of differences that are large enough to be psychologically meaningful in the resultant orderings of the respondents? This is the crucial empirical question that must be asked of the proponents of the structure-of-intellect model. Thorndike (1963a, 1963b) and Wallach and Kogan (1965a) have argued that Guilford's divergent-thinking measures do not correlate with one another more strongly than the degree to

which they correlate with measures of convergent thinking. If this is the case, one would have to conclude that the creativity assessors devised by the Guilford group have nothing more in common than their correlation with traditional intelligence measures. The warrant for claiming the separate existence of one or more cognitive dispositions that should be graced with the name of creativity or divergent thinking as distinct from intelligence therefore would be difficult to find. This dimensionality issue, however, must be subjected to closer scrutiny, for it lies at the very heart of the Guilford group's research enterprise.

To put the issue in perspective, we must return briefly to the history of intelligence testing. In the course of that history can be found a controversy between those who emphasized the existence of a single, broadly defined dimension of ability—the G factor—and those interested in demonstrating the existence of a variety of distinguishable “primary mental abilities” (see Thurstone, 1936, 1938, McNemar, 1964, Vernon, 1965). More recently, these positions have become blurred, as, on the one hand, various “specific factors” come to surround G, and, on the other, a factoring of the “primary mental ability” factors is found to yield a single “second-order” factor that accounts for most of the variance in the former (see, e.g., Burt, 1954, 1958). As Thorndike (1963b) puts it

Although there is a degree of specialization of intellectual functioning, so that tests within a specific region of content or process correlate more highly than those from different regions, still the correlations across regions are appreciably positive. It is these uniformly positive correlations, whether conceptualized as G, or a second-order factor among the primary factors, or as an overlapping of group factors, that give some substance to the general concept of abstract intelligence. (pp. 46–47)

An example of the evidence on this point is provided by Kennedy (1960), who isolated for study a group of 40 adolescents from a pool of 5000 applicants on the basis of proficiency in mathematics. Specific selection of this kind in terms of mathematics skill was found to yield a group that was extremely

high on all of a variety of measures of verbal and of performance intelligence. The strongly unitary character of general intelligence in terms of high intercorrelations among different kinds of assessment thus is demonstrated. Similar findings by Wallach and Kogan (1965a) point to high intercorrelations for 151 fifth graders among measures of verbal aptitude, mathematical aptitude, and verbal and quantitative academic achievement. Another instance is provided in a recent study of adolescents by Hoepfner, Nihua, and Guilford (1966). Evidence for a large variety of separate factors within the general intelligence domain is claimed, yet inspection of the test intercorrelations indicates a high order of relationship among the vast majority of pairs of variables.

The result is that a ranking of individuals in terms of one measure of intelligence or convergent thinking will have a high degree of correspondence with the ranking that will result from application of another such measure. Still, there will be some differences, and Guilford would propose that these differences are of predictive significance. Recent articles by McNemar (1964) and Vernon (1965), however, have argued persuasively that no grounds exist in terms of predictive validity for the making of any further ability distinctions beyond a G factor within the general intelligence domain. In terms of predicting outside criteria of almost any practical kind, in other words, a reliable index of general intelligence does just about as well as a measure of any more specific thinking characteristic that lies somewhere within the general intelligence area.

In the absence of clear support for making distinctions among conventional intelligence or convergent thinking abilities, we must ask, then, if there is an empirical warrant for making *any* distinction at all between such abilities and those described in terms of divergent thinking, before turning to the Guilford group's even more extreme claim that a number of divergent-thinking abilities can be usefully distinguished from one another. The ideal state of affairs would exist if one had adequate criteria of creative accomplishments in hand, against which one could then evaluate purported assessors of divergent thinking. Such criteria are hard to come by within the age range bounded by young adulthood, how-

ever, studies concerned with thinking processes that may be implicated in creativity have concentrated on this age range. We thus are forced to consider first correlations among the measures of divergent and convergent thinking themselves.

Factor analysis as such, the research tool upon which the Guilford group depends for examining these correlations, does not seem to provide a satisfactory way of answering the dimensionality question. Guilford (e.g., 1956) assumes that any factor emerging from the application of his tests which does not seem to be specific to the tests defining it ought to be included in his psychological model. It is extremely unlikely, however, that the 100 or so factors that can be isolated in this manner represent predictively useful distinctions. To follow Guilford's practice of using the statistical separability of factors as the ground for claiming the psychological distinguishability of traits or dispositions thus does not seem defensible. Distinctions of some kind can, after all, be made almost without end, depending simply upon how refined is the choice of tests administered to the respondents. Thorndike (1963a, 1963b) and Wallach and Kogan (1965a) therefore propose a somewhat different approach to the dimensionality question. They argue that the warrant for claiming an empirically separable divergent-thinking domain depends—once the matter of face validity is taken care of—upon showing that the divergent-thinking tasks share a substantial amount of variance in common, that they share substantially less variance with convergent-thinking tasks than they share with one another, and that the measures of convergent thinking share a substantial amount of variance in common as well.

The formulation just described differs, really, in only one major respect from that advanced by the Guilford group. Both approaches to the dimensionality issue must, after all, be based upon some prior theorizing concerning what cognitive measures to include in one's assessment attempts. They do not therefore differ in this regard. The basic difference is that the stipulations that there be "substantial" amounts of shared variance among measures within both the divergent and the convergent-thinking domains, and of unshared variance between the two domains,

represent a more conservative basis for defining a dimension than does the statistical criterion used in factor analysis of the Guilford variety. The statistical rule in question settles for only a minimal amount of distinguishable variance in common, whereas the alternative formulation asks for considerably more than that. Why does it seem appropriate to require a conservative basis for claiming the separability of divergent thinking as a process or set of processes? Because in the absence of clear external validating criteria for divergent-thinking abilities, our primary empirical ground for defending their separate status rests upon their distinguishability from conventional intelligence measures in terms of the orderings of individuals that are obtained. Recall that little empirical warrant can be mustered for the psychological utility of distinguishing among the small differences in orderings of respondents that result from the application of one or another measure in the general intelligence domain. In the light of that outcome, we must be suspicious indeed when a whole class of thinking operations is proposed, under the name of divergent thinking or creativity, as separable from the processes measured by conventional intelligence tests.

What is the evidence, then, concerning the dimensionality of the factors that Guilford and his associates take as contributing to creative thinking? In the two sections that follow we shall consider studies with young adults and with children that have been carried out by the Guilford group or by others using essentially the same divergent-thinking measures. In exploring this research we shall inquire, first, to what degree the divergent-thinking factors cohere, despite their differences, as a relatively unified dimension and, second, whether this dimension in turn can be distinguished from the factors that have been identified with convergent thinking. We have found that convergent-thinking factors possess sufficient variance in common to justify assigning them to a single dimension of individual differences—that of general intelligence. The creativity domain, on the other hand, may or may not constitute a unitary dimension. If not, then we must consider whatever subparts emerge, and ask for each subpart whether it shows a substantially greater degree of internal consistency than the degree

to which it correlates with measures of convergent thinking

Studies with Young Adults Thorndike (1963b) has subjected studies by the Guilford group to reanalysis along the lines that we have been considering. His procedure was to take the two tests possessing the strongest loadings on a given factor as representative of that factor, and he has distinguished between divergent- and convergent-thinking factors in accordance with the Guilford group's concepts concerning these abilities. Thorndike compares the magnitudes of the average correlation among tests representing convergent thinking, the average correlation among tests representing divergent thinking, and the average correlation between these two groups of tests. In the first of two studies analyzed in this manner by Thorndike, results by Guilford and Christensen (1956) were considered. From the Guilford and Christensen factor analysis there emerged three factors in the convergent-thinking domain: "verbal comprehension," "general reasoning," and "education-verbal correlation." Five other factors that emerged were taken by Guilford and Christensen to refer to divergent thinking: "word fluency," "associational fluency," "ideational fluency," "expressional fluency," and "originality." Taking the two highest-loading tests to stand for each factor, Thorndike found that the average correlation among the convergent-thinking measures was .43, the average correlation among the divergent-thinking measures was .27, and the average of the correlations between these two sets of measures was .24. Thus the divergent-thinking measures have little variance in common apart from the variance that they also share with the convergent-thinking domain.

A comparable analysis was carried out by Thorndike (1963b) of a study by Wilson, Guilford, Christensen, and Lewis (1954). Here the Guilford group found evidence for six factors of convergent thinking and eight factors taken to reflect divergent thinking. The convergent-thinking factors were "verbal," "numerical," "perceptual," "visualizing," "reasoning," and "closure." The divergent-thinking factors were "word fluency," "associational fluency," "ideational fluency," "spontaneous flexibility," "adaptive flexibility," "redefinition," "originality," and "sensitivity to

problems."¹ With the two highest-loading tests again taken to represent each factor, Thorndike found the average correlation among the convergent-thinking tests to be .23, the average correlation among the divergent-thinking tests to be .14, and the average correlation between the two domains to be .12. Thus the divergent-thinking tasks again are found to have little variance in common apart from the degree to which they are also related to the convergent-thinking tasks.

By using a procedure identical to Thorndike's, Ward (1966) reanalyzed the data from yet a third study by the Guilford group and obtained the same results. For a study by Guilford, Fick, Christensen, and Merrifield (1957), the average correlation among the convergent-thinking measures was .24, the average correlation among the divergent-thinking measures was .18, and the average correlation between these domains was .15. All of the studies that we described utilized young adult males as subjects. None of them found correlations among divergent-thinking factors to be appreciably higher than those between divergent- and convergent-thinking factors.

Although divergent thinking as a whole therefore does not seem to be distinguishable from convergent thinking, might some subset of the tasks defining the divergent-thinking domain turn out to be distinguishable in this regard? With this question in mind, let us first return to the evidence already considered, and then go on to further studies. The divergent-thinking factors fall, as noted earlier, into three groupings: four concerned

¹ Strictly speaking, the factor of "sensitivity to problems" is considered an evaluative rather than a divergent-thinking factor by the Guilford group, yet they believe it to be relevant to creativity in thinking. Sensitivity to problems concerns the ability to describe problems or difficulties that may arise in connection with various situations. Its tests are rather similar in fact to some of those used to tap the factor of "ideational fluency." Thus, although all the factors that are taken to reflect divergent thinking are considered by Guilford to be relevant to creativity, an occasional factor defined as outside the divergent-thinking domain also has been discussed by Guilford in relation to creativity. With but an occasional exception such as this, however, Guilford takes the term "creativity" to be roughly synonymous with his set of divergent-thinking factors.

with fluency, three with flexibility, and one with originality. We again take the two highest-loading tests to represent a factor, and draw upon reanalyses of the Guilford group's studies by Thorndike (1963b) and Ward (1966).

Turning first to fluency, recall that Guilford and Christensen (1956) obtained four fluency factors. Their average intercorrelation is .29, whereas the average correlation between the fluency factors and the convergent-thinking domain is found to be .24. Three fluency factors emerged in the study by Wilson et al. (1954). Their average intercorrelation is found to be .23, and their average correlation with convergent thinking, .14. In the study by Guilford et al. (1957), only one fluency factor was found—ideational fluency—and its correlation with the convergent-thinking domain turns out to be .01. Some evidence begins to emerge, then, for the distinguishability of the fluencies from convergent thinking. Thorndike (1963b), furthermore, has pointed out that in both the study by Guilford and Christensen and that by Wilson et al., the word-fluency factor actually correlates more strongly (in the latter study, twice as strongly) with the convergent-thinking domain than with the divergent-thinking domain. Thorndike therefore suggests, although admittedly this is *post hoc*, that we delete word fluency from the divergent-thinking domain. Following his prescription, the three remaining fluency factors in the Guilford and Christensen study are found to correlate .31 among themselves and .22 with convergent thinking, whereas the two remaining fluency factors in the Wilson et al. study are found to correlate .28 among themselves and .08 with convergent thinking. Perhaps therefore the fluency factors—especially if one deletes word fluency—correlate more strongly among themselves than they do with convergent thinking.

Turning next to flexibility, the studies by Wilson et al. (1954) and by Guilford et al. (1957) each yielded three flexibility factors. In the Wilson group's research, the mean correlation within the set of flexibility factors was .13, while that between the flexibility factors and convergent thinking was .15. In the Guilford study, the corresponding mean correlations were .24 and .20, respectively. Taking both studies together, the flexibility factors thus do not seem more strongly related among

themselves than the degree of their relationship with convergent thinking.

Originality, finally, is defined only by a single factor in Guilford's model. In the three studies that we have been considering, the tests representing this factor are found to possess average correlations with general intelligence of .25 (Guilford and Christensen, 1956), .01 (Wilson et al., 1954), and .19 (Guilford et al., 1957). On balance, then, there do not seem to be clear grounds for considering originality distinguishable from convergent thinking.

The conclusion thus far appears to be that although the divergent-thinking domain *in toto* is not distinguishable from convergent thinking, one part of that domain—the fluency factors, especially with word fluency deleted—may be distinguishable in some degree. No evidence, in turn, for the distinguishability from intelligence of the flexibility factors or of originality could be claimed. With these tentative generalizations in hand, we proceed to other reports for further clarification.

In a detailed study of the originality domain as Guilford would define it, Barron (1955, 1957, 1963) administered to 100 young male adults eight tasks designed to probe the domain in question. Included, for example, was an unusual-uses procedure scored for infrequency, in the sample under study, of the uses proposed, a consequences procedure in which the subject was to write down what would happen if certain changes were suddenly to occur, with the scoring in terms of how nonobvious were the imagined consequences, and a plot titles instrument in which, for each of two story plots, the subject was to write as many titles as possible, with the titles then scored for cleverness (see Guilford, Wilson, Christensen, and Lewis, 1951; Guilford, Wilson, and Christensen, 1952). The average of the 28 correlations among all possible pairs of originality measures was found to be .19. A composite originality score was constructed by summing the standard scores on all eight measures, and this composite was found to correlate .33 with a general intelligence index—the Terman Concept Mastery Test. Whatever major dimensionality the originality measures possessed therefore was accountable for in terms of the measures' correlation with convergent thinking.

Barron went on, however, to partial out the

effects of intelligence as defined by the Concept Mastery Test from his composite originality score, and then to study the relationships that remained among the composite score and a range of other variables that had been gathered on the sample during the course of a 3-day "living-in" assessment regime. And here an intriguing finding emerged: with the effects of intelligence partialled out, the major cognitive dimension that remained in terms of partial correlations with the originality composite appeared to be best definable as something like ideational fluency. Comprising the dimension were such measures as the number of kinds of idea discerned in sets of varied objects and properties, the number of different determinants made use of in one's Rorschach responses, degree of fluency and motility in acting out a charades task, degree of participation in an improvisation task, and a staff rating provided for fluency of ideas. Part of the tendency to give unusual or original responses, then, seems to arise as a function of greater response fluency or productivity, and this part, along with fluency or productivity itself, seems to be separable from convergent thinking.

Additional evidence along the same lines was reported by Christensen, Guilford, and Wilson (1957), here uncommonness of uses and remoteness of consequences were found to be greater for later than for earlier responses in the sequence produced by the subject. Interestingly enough, cleverness of plot titles was not found to vary with number of responses in this way, suggesting a distinction within the originality domain between forms of originality that are dependent upon fluency of output and forms that are not. Those dependent on fluency of output seem to concern statistical infrequency of content, whereas those not dependent seem more concerned with verbal facility.

A recent study by Garwood (1964) casts further light on the empirical link between ideational fluency and originality of content when they are investigated by similar procedures. With 105 young adult male students as subjects, two measures—the total number of feasible uses offered, and the total number of feasible uses that were fully unique in the sense of their being offered as a use for the given object by only one person in the sample—were strongly correlated in an alternate-

uses task in which the respondent was to list uses other than the primary one for common objects (Wilson, Christensen, Merrifield, and Guilford, 1960). Similarly, two measures correlated strongly in a consequences task where the subject was to list all the consequences he could imagine if each of various proposed changes were to occur (Christensen, Merrifield, and Guilford, 1958); these measures are the total number of relevant consequences offered and the total number of suggested consequences that were remote, that is, temporally or geographically distant. That the measure of unusual responses correlated with the measure of total number of responses within a given procedure of course would be expected on analytic grounds because of the part-whole relationship between the scores. The measure of unusual responses on either procedure, however, also correlated substantially with the measure of total number of responses on the other, thus supporting the view already fostered by the Barron and the Christensen et al. (1957) results that there is an aspect of originality which is in fact tied to fluency of output.

But does Garwood's work provide any evidence on the issue of relationships to convergent thinking abilities? Regrettably, her final creativity measure was a composite which also included scores on other Guilford-type tasks, such as a matchstick procedure designed to assess the factor of adaptive flexibility (Marks, Guilford, and Merrifield, 1959) and a Gestalt transformations procedure in which the respondent had to indicate which of a set of objects could best serve a specified purpose alien to the customary usage of the objects—a measure for assessing the factor of redefinition (Guilford, Wilson, and Christensen, 1952). These flexibility assessors had weak and ambiguous correlations with the fluency and originality indices discussed earlier. With our previously formed suspicion that measures of flexibility factors may not be distinguishable from the convergent-thinking domain, we are not surprised to find that Garwood's composite creativity index showed some degree of relationship to general intelligence indicators. It would be interesting to know, of course, if the relationship with intelligence would disappear in a comparison involving the measures of ideational fluency in particular.

Studies with Children and Adolescents

Our review continues with studies concerning the Guilford group's tasks as applied to somewhat younger subjects. Where the "adolescent" grouping of this section ends and the "young adult" grouping of the previous section picks up is partly an arbitrary matter, we take this point roughly as corresponding to the student's leaving high school.

Cline, Richards, and Abe (1962) and Cline, Richards, and Needham (1963) administered to high school students of both sexes a battery of tasks designed to tap a range of divergent-thinking factors. The creativity indices, as taken from the Guilford group's work, provided measures of ideational fluency, associational fluency, spontaneous flexibility, adaptive flexibility, redefinition, and originality. California Mental Maturity Inventory scores provided an intelligence measure, and grade point averages also were collected. In the Cline, Richards, and Abe study, the average correlation among the divergent-thinking measures was .21 for males and .22 for females, while the average correlation between the divergent-thinking indices and intelligence was .35 for males and .32 for females. In the Cline, Richards, and Needham study, the comparable correlations were .21 and .24 for males and females, respectively, within the divergent-thinking domain, .35 and .33 for males and females, respectively, between divergent thinking and intelligence. Results were essentially the same if we consider the measures of fluency, flexibility, and originality as separate subgroups. Data on academic achievement were found, in the work by Cline and his collaborators, to behave like intelligence scores: correlations between grade-point average and the creativity tasks are if anything stronger, on the average, than correlations among the divergent-thinking tasks themselves. As would be expected from this outcome, intelligence and grade-point average are in turn quite highly related. In sum, both of these studies, using a broad range of divergent-thinking tasks, did not find the Guilford procedures as a group, nor any relevant subgroup of these procedures, cohering to a degree that suggested their possessing any common psychological meaning apart from what was indicated by their correlating with general intelligence or academic achievement, that is, convergent thinking.

Other studies that tended to yield either negative or ambiguous findings concerning the divergent-thinking-convergent-thinking separation include the following. Iscoe and Pierce-Jones (1964) found, for 267 children of ages 5 to 9, that most of a large number of correlations between a set of intelligence measures on the one hand and measures of ideational fluency and spontaneous flexibility on the other turned out to be significant. Klausmeier, Harris, and Ethnathios (1962) investigated several fluency measures in relation to teacher ratings for the kinds of fluency under consideration, with almost 200 tenth and eleventh graders as subjects. Although moderate positive relationships were obtained between the teacher ratings and the fluency indices, no examination of possible relationships to general intelligence was carried out. Given the possibility of halo effects from intelligence information as an influence upon the teachers' ratings, it could well be that the degree of relationship obtained between fluency ratings by teachers and fluency scores on the tests depended on variance shared by each of these indicators in the present study with intelligence. In another study, Klausmeier and Wiersma (1964) administered a heterogeneous range of divergent thinking tasks to fifth and seventh graders, but they did not investigate the relationships among these tasks or the degree of their relationship to intelligence indicators. Anderson (1966), in an extensive investigation of seventh graders, found a range of convergent-thinking tasks to separate in some degree from a range of divergent-thinking tasks, but he then found individual differences on the convergent-thinking composite score to correlate .51 with individual differences on the divergent-thinking composite score—a very substantial correlation indeed for a sample of 320 children. Compared to a number of other variables that were studied, the most powerful predictor by far of scores on the divergent-thinking composite index turned out to be scores on the convergent-thinking composite index.²

A number of reports can be located, however, which suggest the separability from convergent thinking of one part of the divergent-thinking domain as Guilford defined it once

² See also Cropley, 1966.

again, it is ideational fluency this work tends to point toward

Research by Gewirtz (1948a, 1948b) and by Bereiter (1960, 1961) helps to clarify the detachment of word fluency from the divergent thinking domain and its assignment rather to the general intelligence category. With children of ages 5 to 6½ years, Gewirtz (1948a, 1948b) found measures of the word fluency variety to intercorrelate strongly among themselves and also with a Stanford-Binet measure of intelligence. Other fluency tasks, closer in character to the Guilford group's definition of ideational fluency, on the other hand, have been found in Bereiter's (1961) reanalysis of the Gewirtz data to load heavily on a factor to which the Stanford-Binet measure makes no contribution at all. The tasks found to load heavily on this intelligence-free factor included a measure of the child's naming as many objects as possible and a measure of the number of different words used by the child in describing his house. Such indices would seem to depend in fair degree upon the number of ideational possibilities that the child can conjure up. In a study of over 250 tenth graders, Bereiter (1960) in turn found no clear warrant for viewing verbal and ideational forms of fluency as having much in common psychologically. One therefore begins to glimpse the possibility that not only should word fluency be banished from the divergent thinking category but that the concept of ideational fluency may be paradigmatic for the kind of cognitive performance that is maximally cohesive in itself and maximally distinguishable from convergent thinking.

Using a range of Guilford divergent-thinking tests with a sample of 114 seventh and eighth graders, Piers, Daniels, and Quackenbush (1960) found the average correlation among the divergent-thinking indicators—including measures of both originality and ideational fluency—to be .26, while their average relationship with the Otis Intelligence Test was .19. However, separation of the divergent-thinking tasks into those concerned with originality and those concerned with ideational fluency yielded a different picture. The four measures designed to tap originality exhibited an average correlation of .37 among themselves and an average correlation of .31 with intelligence. The three measures designed to tap ideational fluency, on the other hand, al-

though also showing a satisfactory degree of internal coherence with an average correlation of .36 among themselves, manifested an average correlation of -.03 with intelligence. Thus, whereas the originality indicators correlated to about the same degree with intelligence as they did among themselves, the ideational fluency measures correlated substantially among themselves but not at all with general intelligence.

With a sample of more than 1000 seventh graders, McGuire, Hindsman, King, and Jennings (1961) administered, among other tasks, such "convergent-thinking" indicators as the California Test of Mental Maturity, a Sequential Test of Educational Progress instrument concerned with the comprehension of verbal passages and questions that were read aloud (the STEP "listening" test), and a test concerned with the ability to reason about pictorially presented mechanical situations. Also administered were such presumed "divergent-thinking" indicators as a word fluency task in which the subject was to write words that rhyme with given words, the Gestalt transformations task as a measure of the factor of redefinition, an ideational fluency indicator in which the subject was to list different possible consequences of various proposed changes, and another ideational fluency measure in which the subject was to list possible problems suggested by various common situations (see Fick, Guilford, Christensen, and Merrifield, 1959; Guilford, Wilson, Christensen, and Lewis, 1951; Wilson, Guilford, and Christensen, 1953; and Wilson, Guilford, Christensen, and Lewis, 1954).

Two strong factors that differentiated the preceding measures in a quite intriguing way resulted from analytic rotation to an orthogonal Varimax solution. Following, rounded to the nearest tenth, are the respective loadings on these two factors for the measures just described: California Test of Mental Maturity, .6 and .2; STEP "listening" test, .7 and .2; mechanical reasoning test, .6 and .1; word fluency task, .6 and .3; Gestalt transformations measure of redefinition, .6 and .0; "consequences" measure of ideational fluency, .3 and .6; "common situations" measure of ideational fluency, .2 and .6. Hence we find a clear general intelligence cluster, adhering to which are an indicator of word fluency and an indicator of one of Guilford's flexibility

factors, redefinition. There also emerges, however, another factor that is heavily defined by the ideational fluency measures, which, in turn, have minimal loadings on the general intelligence factor. Not only is a strong separation suggested by these results between ideational fluency and convergent thinking therefore, but we also find two other ostensible measures from the divergent-thinking domain—tasks assessing word fluency and one of the flexibilities—cohering strongly with the convergent-thinking cluster.

In a study of almost 200 students in the 11- to 15-year-old range, Clark, Veldman, and Thorpe (1965) utilized a type of originality scoring that, as we indicated in considering Garwood's (1964) study, has been found to correlate quite highly with ideational fluency. Such Guilford tasks as the "consequences" and "common situations" procedures already described were scored for the number of statistically unique yet relevant responses offered by the subject. When individual differences on such a uniqueness measure were correlated for a sample of both sexes with total IQ scores on the California Test of Mental Maturity, the result was an r of only .04. Here is suggestive evidence once again, then, that measures in and around the ideational fluency domain may be relatively independent of convergent thinking. The present study is less than conclusive, however, since, contrary to what we would expect, a reading achievement measure correlated with the uniqueness index rather than with the intelligence index. On the other hand, various Rorschach indicators reflective of the degree to which the respondent gives free rein to imaginative production were found to correlate with the uniqueness index and not with the intelligence index, these indicators included the number of movement responses given and the incidence of signs presumed to reflect anxiety. The perception of movement in Rorschach patterns and scores on measures that have been assumed to indicate "anxiety" will be of interest to us later in the chapter.

A set of 10 measures, designed to tap ideational fluency, spontaneous flexibility, and originality, was utilized in a recent study by May and Metcalf (1965) concerning eighth-grade students. Correlations among these measures were presented, as were their relationships with an intelligence index—a "ver-

bal reasoning test" containing verbal analogy items. Taking first the three ideational fluency measures, correlations among them averaged .60, whereas their average correlation with the intelligence measure was .04. Turning to the three measures of spontaneous flexibility, the average correlation among them was .41, whereas their average correlation with intelligence was .13. The four originality measures, finally, yielded an average correlation of .23 among themselves, and an average correlation of .17 with intelligence. Thus it is the ideational fluency indices therefore that show the strongest coherence among themselves and also show the greatest independence from intelligence.

Feldhusen, Denny, and Condon (1965), in another recent report, utilized an alternate uses task as the basis for assessing spontaneous flexibility, while using a consequences procedure as the basis for assessing both ideational fluency and originality. Seventh and eighth graders were the subjects. Indicators of both intellectual aptitude (the School and College Ability Tests) and academic achievement (the Sequential Tests of Educational Progress) were available as convergent-thinking assessors. Ideational fluency was found to be independent of the SCAT and STEP measures for both sexes. Spontaneous flexibility, on the other hand, was found to be related to the SCAT and STEP measures for both sexes. Originality, finally, turned out to be related to the convergent-thinking indicators for the boys but not for the girls. Once again, then, ideational fluency was essentially independent of convergent thinking.

Finally, consider a paper by Orpet and Meyers (1966) concerned with 100 6-year-olds. Within the divergent-thinking domain, only tasks dealing with ideational fluency were administered. Various general intelligence assessors, however, also were included in the battery. From a factor analysis with an orthogonal Varimax rotation there emerged a clear factor whose highest loadings were provided by the four tasks that were taken to represent ideational fluency. At issue in all of these tasks was the number of acceptable ideational responses produced by the child. Loadings for these tasks ranged from .57 to .66 on the factor in question. By contrast, typical intelligence measures have loadings that do not exceed .30 on the ideational fluency fac-

tor Turning to the factor on which the WISC vocabulary and WISC comprehension subtests both have their highest loadings (.71 and .69, respectively), the four ideational fluency tasks have loadings that range from .02 to .22. Considerable separation seems to exist here, then, between ideational fluency and typical intelligence measures.

The Evidence in Retrospect In this part of the chapter we have been considering evidence bearing on Guilford's divergent-thinking formulation where the operations utilized have been taken directly from the Guilford group's work or have stayed very close to the procedures devised by Guilford and his associates. Several generalizations have emerged from passing this evidence in review. Most clearly supported as a dimension of individual differences independent from the convergent-thinking domain but also cohesive in its own right when one measures it in different ways has been what Guilford defines as ideational fluency—the person's ability to generate in plentiful number ideas that are appropriate to a given task constraint. Fluency with respect to words instead of ideas, which Guilford defines as the word-fluency concept, seems to have much more in common with general intelligence than with ideational fluency. One also begins to suspect that insofar as the other two fluency concepts dealt with by the Guilford group—associational and expressional fluency—move closer in particular task materials to tapping facility with words, they will end up more strongly aligned with general intelligence, whereas insofar as particular task contents for those concepts move closer to tapping facility with producing ideas as distinct from specific verbal trappings, the concepts will end up more strongly aligned with ideational fluency. Among the fluencies, in other words, as well as among all the divergent-thinking characteristics that have been proposed, it is the ideational fluency notion that seems to define the kind of cognitive functioning that is most clearly independent of convergent thinking.

Little evidence, in turn, supports the tenability of viewing any of the three flexibility concepts—spontaneous flexibility, adaptive flexibility, and redefinition—as more cohesive in its own right than the degree to which that concept merges with general intelligence. The set-shifting ability that these concepts imply

is more closely identified empirically with the traditional intelligence domain than with some different kind of functioning that might properly be considered an aspect of creativity.

In considering the originality concept, finally, the situation seems more ambiguous. Sometimes the originality indicators seem to be more related to convergent thinking, sometimes less so. We begin to suspect that the originality concept therefore may not have been defined with maximum clarity in its initial formulation by the Guilford group. In fact, the drift of the evidence suggests that originality measures may turn out to be more independent of intelligence to the extent that they correlate with ideational fluency measures, and more related with intelligence to the extent that they are independent of ideational fluency measures.

It may be that originality measures will tend to exhibit independence from intelligence if they depend upon assessing the uniqueness or unusualness of the ideas that a person generates, whereas they will tend to show relationships with intelligence if they depend upon a judgment of cleverness or facility in choice of words for expressing one's ideas. The kind of originality that is independent of intelligence, then, may be the kind that is facilitated by high ideational fluency: unusual or unique ideas are likely to occur later in a sequence of responses to a given task, so that the more plentiful the person's flow of ideas, the more likely he is to hit upon original ones. The giving of unusual uses for a brick, or of remote consequences as possibilities to which a particular event may lead, would be more likely to the extent that the respondent offers a larger number of uses or suggests a larger number of consequences to begin with. The kind of originality that correlates with intelligence, on the other hand, may be the kind that resides in sheer cleverness of verbal expression, which should depend heavily upon vocabulary size. The offering of plot titles that seem more out of the ordinary and hence earn higher "cleverness" scores may constitute an example of this second meaning for originality.

One final point should be emphasized. The vast majority of the studies that we reviewed administered the "divergent-thinking" tasks with relatively brief time limits and in an ability-testing context, that is, group admin-

istration in a classroom. As we pointed out earlier, however, emphasis upon speed of response and presence of the implication that there are correct answers would not seem to have an appropriate part in attempting to assess a person's talent for thinking in divergent ways. Were the task contexts less evaluative and the time limits more lenient or even nonexistent, therefore, the evidence for the independence from intelligence of ideational fluency and of forms of originality that are related to such fluency might have been even stronger.

DIRECT DESCENDANTS OF THE GUILFORD TRADITION

Two lines of further research stem directly from the work of the Guilford group, in the sense of leaning heavily upon that group for deriving a number of procedures, and also in the sense of sampling a comparably broad range of cognitive skills as presumably constituting what should be defined as creativity in thinking processes: the program of E. P. Torrance and the work of Getzels and Jackson. Both of these lines of research differ from most of what has already been considered, on the other hand, in that they both devote attention to the developing of further assessment procedures. We turn first to the work of Torrance and of other investigators who have utilized his assessment devices. Then, in the next part of the chapter, we shall consider the work of Getzels and Jackson.

Torrance's Studies and Related Work

Theoretical Considerations. Torrance defines creative thinking as "a process of becoming sensitive to problems, deficiencies, gaps in knowledge, missing elements, disharmonies, and so on; identifying the difficulty, searching for solutions, making guesses, or formulating hypotheses about the deficiencies, testing and retesting these hypotheses and possibly modifying and retesting them, and finally communicating the results" (Torrance, 1966a, p. 6). Thus Torrance considers the entire problem-solving sequence, in its broadest sense—from detecting a problem to communicating one's solution—to be the appropriate referent for the notion of creativity in thinking processes. It is difficult, as a matter

of fact, to detect much clear divergence between the foregoing definition and customary views of what intelligence involves. For example, compare this to Wechsler's definition of general intelligence: "Intelligence is the aggregate or global capacity of the individual to act purposefully, to think rationally and to deal effectively with his environment" (Wechsler, 1952, p. 3). The Torrance definition seems to include everything contained in Wechsler's, but to add explicit references to divergent thinking "searching for solutions, making guesses, or formulating hypotheses."

Thus what Torrance seems to mean by creativity is a general intelligence concept liberalized by the addition of references to a problem-solution phase in which it is useful for thinking to go off in different directions. If anything, then, Torrance's concept of creativity is even broader than that of Guilford, since Torrance's seems to imply a single basic dimension of which both divergent and convergent thinking would be parts.

What are Torrance's procedures for probing creativity? Some of his assessment devices involve verbal, others figural materials. Although the various tasks are intended to tap somewhat diverse functions, the customary practice of Torrance and his followers is to derive a single overall creativity index score—or, at most, one summary score for the verbal tasks and another for the visual—and to take the index score as signifying the subject's level of creative functioning. The various verbal and figural procedures are, as far as possible, all subjected to the same four types of scoring for fluency, flexibility, originality, and elaboration (Torrance, 1966a, 1966b, 1966c). The first three of these scoring concepts already are familiar to us from the work of Guilford, regarding the first two, it is ideational fluency and spontaneous flexibility that are meant. Torrance's use of a common set of scoring templates for his tasks contributes further, of course, to the impression that, although he sometimes describes them as dealing with various psychological characteristics, they in fact are treated as functionally equivalent. Thus scores for fluency, flexibility, originality, and elaboration will be summed across all the verbal and/or all the figural tasks, and then these four totals are summed in turn into the single index score.

The administration context for the proce-

dues is similar to that described for the Guilford tasks. The various tasks are timed and given relatively brief time limits. Torrance would have the typical administrator of the procedures be the teacher, so that whatever evaluative connotations are conveyed by her role will be present for the creativity instruments. In the research involving these tasks, furthermore, group administration typically prevails, although Torrance does recommend individual administration from the kindergarten to third-grade levels. Finally, a further feature reminiscent of convergent-thinking situations that even goes beyond the typical instructions for the Guilford tests is to be found in Torrance's instructions: a subtle implication to the respondent that some answers are more correct than others, and that the ones to be preferred are the ones that are more unusual and clever.

Here is an overview of one of two alternate parallel sets of test materials that Torrance (1966b, 1966c) has developed. The battery includes seven verbal tasks—a three-part “ask-and-guess” test, product improvements, unusual uses, unusual questions, and the “just suppose” activity—and three figural tasks—picture construction, incomplete figures, and parallel lines.

In the *ask-and-guess* test, the subject is shown a picture of a clownlike figure viewing his reflection in the water. With 5 minutes to devote to each task, the subject is first to write down all the questions he can think of about the picture, second to list as many possible causes as he can of the situation depicted in the picture, and third to list as many possible consequences of the depicted situation as he can. As to scoring, the number of relevant responses offered defines the fluency variable, the number of spontaneous shifts from one category to another regarding the kinds of questions, causes, and consequences presented defines flexibility, the statistical infrequency of the responses defines originality, and the amount or degree of detail and specificity incorporated into the responses defines elaboration.

For the *product improvement* task, a toy stuffed elephant is shown to the respondent, and he is given a set time period in which to list all the most clever and unusual ways he can think of for changing the toy to make it more fun for children to play with. Here again

and in the remaining procedures as well, except where otherwise noted, scoring is carried out for fluency, flexibility, originality, and elaboration in ways analogous to those described for the ask-and-guess test.

The *unusual uses* procedure requests the respondent to indicate, in a set time, as many interesting and unusual uses as he can imagine for cardboard boxes.

In the *unusual questions* task, the subject is to think of as many intriguing questions as possible that one can raise concerning cardboard boxes. Only fluency and originality are scored for this procedure.

Finally, the *just suppose* activity requires the subject to entertain a particular improbable situation and describe all the events that its occurrence would entail. The situation in question is clouds having stings attached that hang down to earth.

Turning to the figural tasks, the *picture construction* instrument presents the respondent with a piece of green paper in an egg-like shape, which he is to glue wherever he wishes on a blank page, then adding lines so as to incorporate this shape into a picture that will be as clever and imaginative as possible. The product is scored for originality and elaboration.

For the *incomplete figures* procedure, the subject is confronted with different schematic line forms, to each of which he is to sketch additions to represent a picture or object that is as unusual as possible.

The *parallel lines* task is similar to the preceding procedure, except that all the presented line forms that the subject must work from are the same—a pair of parallel straight lines.

In reviewing research that has utilized Torrance's tests, the major question we must address is, once again, the dimensionality issue. Do the Torrance procedures define a dimension of individual differences that is cohesive to a substantially greater degree than the degree to which those procedures correlate with measures of general intelligence?

Relationships with Intelligence and Academic Achievement. Evidence already has been noted to the effect that customary measures of intellectual aptitude and of academic achievement seem, at least during the childhood and adolescent years, to be very substantially correlated. To cite examples of still

further data to this effect, Edwards and Tyler (1965) found for the 181 ninth graders in a given school system that the correlation between performance on the School and College Ability Tests (a general intelligence measure) and performance on the Sequential Tests of Educational Progress (an academic achievement measure) was .86. They furthermore reported that the children between the intelligence index just cited and the students' grade point average was .66. From such findings we can surmise that studies of the relationship between the Torrance tests and academic achievement will, at least in large measure and perhaps entirely, actually be examining to what extent the Torrance battery is related to general intelligence. For this reason, it seems appropriate to consider work on achievement and on intelligence correlates of the Torrance tests under a common heading.

There is little direct evidence explicitly comparing the magnitudes of relationships among the Torrance measures with the extent of relationship between those measures and intelligence indicators—the type of issue we studied at length in considering Guilford's tasks. This lack seems to derive from the heavy dependence upon use of one or another overall creativity index score by those who have worked with the Torrance tests. Perhaps the most extensive evidence on the issue derives from a study by Cicirelli (1964) of more than 600 sixth graders. If we consider the correlations between all possible pairs of eight summary variables that were derived—fluency, flexibility, originality, and elaboration scores for a verbal and a figural battery—the average r turns out to be .37. This number, however, represents an artifactually inflated value to some degree, because, as we noted earlier in discussing Garwood's study, total number of ideas and number of relatively unique or unusual ideas as derived from the same procedure—the fluency and originality variables—possess a whole-part relationship to each other. As a result, some magnitude of positive correlation is guaranteed between fluency and originality scores. Cicirelli also reported correlations between the creativity indicators and various intelligence and achievement measures, such as the California Mental Maturity IQ index and California Achievement Test scores for reading, arithmetic, and language. All correlations were significant and

tended to fall in the 20s and 30s. If we estimate the effect of removing the spurious inflationary component from the average r of .37 among the creativity scores, the result would be a value quite similar to their degree of correlation with the intelligence and achievement measures.

A number of other studies, although not considering the strength of relationships among the Torrance measures, have reported on relationships between Torrance index scores and intelligence or achievement measures. These relationships, which usually have been substantial, further support the likelihood that the major role of the Torrance tests is to assess conventional forms of intellectual aptitude and academic achievement. Thus, for example, Perry (1966) administered to sixth-grade children a verbal battery of the Torrance tests. These children had been continuously enrolled in the same school since kindergarten. Their creativity index scores yielded significant rho correlations of .54 with the kindergarten administration of the Metropolitan Reading Readiness test, .50 with the fifth-grade administration of the Otis Quick-Scoring Mental Ability Tests, .44, .46, and .59 with the sixth-grade administrations of the Reading Comprehension, Arithmetic Reasoning, and Spelling Achievement tests, respectively, from the Stanford Achievement Test battery, and .55 with an overall academic achievement score derived from the sixth-grade administration of the Stanford Achievement Test battery.

Yamamoto (1965) administered a set of verbal and figural creativity tasks and the verbal battery from the Lorge-Thorndike Intelligence Test to one sample of over 450 and another of over 800 fifth graders. Using a single creativity index score, the correlation with intelligence was .33 in the first sample and .39 in the second, both very substantial for such large samples. Since the first sample represented a socioeconomically homogeneous middle-class group, whereas the second represented a group more heterogeneous in socioeconomic status, we find these kinds of background factors to have relatively little effect upon the creativity-intelligence linkage that was obtained. From our earlier discussion of the Cicirelli findings concerning a comparably large sample of sixth graders, the evident implication to be drawn is that the various

creativity measures constituting Yamamoto's index most likely are no more highly inter-correlated than the degree of correlation between the creativity index and the intelligence measure

Among the numerous further studies providing documentation for the existence of comparably substantial relationships between Torrance procedures and intellectual aptitude or achievement indices, we may cite the following instances. Yamamoto (1964a) reported a significant correlation of .30 between measures of creativity and intelligence for a high-school sample. With children in grades 4 and 5, Wodtke (1964) found that an index combining verbal and figural creativity tasks correlated .44 with an intelligence composite including verbal and nonverbal parts of the Lorge-Thorndike intelligence test among 100 fourth graders, while the comparable correlation was .45 among 100 fifth graders. In a study of fifth and sixth graders, Long and Henderson (1965) even found a significant positive relationship between a figural creativity task and a verbal academic achievement task.

Although occasional exceptions do occur in which Torrance measures and intelligence or achievement indicators are unrelated (Fleming and Weintraub, 1962; Edwards and Tyler, 1965), these can be accounted for in terms of restriction of range for the intelligence assessment, partialling out of age from the intelligence but not from the creativity index, or unreliability of creativity measurement. Thus Fleming and Weintraub (1962) utilized a specially selected sample of "gifted children" with a very high mean IQ (approximately 136) and consequent restriction of IQ range. There also is the problem in the Fleming-Weintraub study that an IQ score was used to measure intelligence with a sample that varied widely in age—from 8 to 12½ years. Since an IQ score partials out the effects of age, the implication is that age was partialled out of the intelligence measure but not the creativity measure, with underestimation of their degree of relationship as a necessary consequence. Edwards and Tyler (1965), in turn, summed a single figural and a single verbal creativity task, even though the figural and verbal domains show relatively low coherence (Torrance and Gowan, 1963), and relationships with intelligence or achievement

criteria are stronger for the verbal than for the figural task (Bish, 1964). In sum, it is fair to state that the clear majority of the studies using Torrance's assessors have found substantial linkages between creativity and measures of intellectual aptitude or achievement.

Having begun with the fact of strong relationships between aptitude and achievement indicators, we have found that Torrance index scores correlate with these in about the same degree to which we can expect the array of Torrance's measures to correlate with one another. No unitary dimension is defined by these measures therefore, apart from that of general intelligence. Hence there is still no cause for assuming the Torrance measures reflect a cognitive disposition that could be appropriately described in terms of creativity. Somewhat paradoxically, Torrance (e.g., 1962, 1963, 1966a) has ignored this dimensionality issue and bases a large part of the defense of his instruments upon their ability to predict academic achievement criteria—despite the demonstrably high relationship between such criteria and conventional intelligence assessors. His argument—the "threshold of intelligence" concept—is that, above a certain level of intelligence, academic achievement is more strongly related to his creativity measures than to further increments of intelligence. Why the prediction of academic accomplishment should be thought to redound to the credit of a purported assessor of creativity, however, is difficult to understand. After all, memorization of rule systems and the ability to manipulate their terms toward the goal of finding a correct answer—hence convergent thinking—constitute the very core of what is required for earning high scores on academic achievement tests. Be this as it may, what kind of evidence would be needed to support the threshold-of-intelligence concept?

Given the sizable correlations found among Torrance's index scores, traditional intelligence measures, and academic achievement yardsticks, there already is the strong presumption, of course, that most of the ability of the Torrance indicators to predict achievement criteria would depend upon the substantial variance shared by the Torrance and the achievement measures with general intelligence. A small amount of further predictability might be expected from the Torrance

instruments, in turn, not because they tap a different cognitive domain from that of general intelligence, but simply because they increase the thoroughness with which convergent thinking abilities are being sampled. To put the matter another way, if a single intelligence measure does a fair job of predicting academic achievement, addition of a second correlated intelligence assessor should increase predictability somewhat just because a more adequate sampling of the abilities that comprise the intelligence domain would thereby be provided. What the threshold-of-intelligence concept requires, on the other hand, is that the predictability of academic achievement be sizably enhanced by adding a creativity assessor when the sample of subjects under study ranges into high levels of intelligence. Let us turn now to some research on this issue.

With more than 600 sixth graders as subjects, Cicirelli (1965) found that most of the ability of the Torrance indices to predict various academic achievement criteria depended on shared variance with intelligence. Thus, of 12 correlations computed between creativity and achievement measures, eight were 2 or better. However, when intelligence was held constant by partialling out IQ scores, only three of the 12 correlations remained 2 or better.

In another study, Yamamoto and Chimbidis (1966) utilized a sample of almost 800 fifth graders, administering the verbal battery of the Lorge-Thorndike Intelligence Test, a battery of verbal and figural creativity instruments from which were derived a single index score, and the Stanford Achievement Test battery. With a mean IQ of 110.3 for the entire sample, a division was made between children with IQ of 121 and above and children with IQ of 120 and below. Relationships between intelligence and achievement scores tended to be substantial for all groups—for the total sample, the lower IQ group, and the higher IQ group—although less strong for this last-mentioned group. When, however, partial correlations were computed between creativity and academic achievement holding intelligence constant, all of the relationships turned out to be near zero. A further indication of how little the creativity scores add to the intelligence scores in predicting

achievement is provided by the following comparison. With correlations combined across a variety of academic achievement areas, we present first the single-order correlation between IQ and achievement, and next the multiple correlation for IQ and creativity as joint predictors of achievement. For the entire sample, the correlation goes up from .56 to .57. For the lower IQ group, the simple and multiple correlations remain the same—.56. For the higher IQ group, the correlation goes up from .22 to .27. On the whole, then, intelligence predicts achievement less well in the high IQ range than elsewhere, but creativity scores do not offer much predictive help anywhere along the IQ continuum.

The relatively small further contribution that is made by the Torrance creativity battery to predicting academic achievement, as distinct from the contribution made by general intelligence, can be given further illustration in the results of a study by Bowers (1966). The subjects, almost 300 ninth-grade pupils approximately equally divided between the sexes, received a creativity battery that included five verbal and two figural procedures, from which was derived an overall creativity index. The academic achievement criteria were grade level and scores on the Iowa Tests of Educational Development. The Otis Quick-Scoring Test of Mental Ability provided the intelligence measure. The single-order correlation between the intelligence measure and achievement was about .6 or .7, whereas the multiple correlation in which the creativity index and the intelligence measure serve as joint predictors of achievement typically was only a few hundredths higher.

In extensive studies of the issue, therefore, the threshold-of-intelligence concept has not been supported by the results obtained. Index scores derived from the Torrance tests behave, in relation to academic achievement, as if they constitute an alternative means for assessing the convergent-thinking domain, not as if they predict academic achievement in subjects of superior intelligence. Given the degree—and it will be substantial—to which a particular intelligence assessor predicts academic achievement, addition of the Torrance battery can be expected to increase predictability only marginally—and, indeed, to no greater an extent than would also be afforded

by the addition of a second measure of general intelligence. The evidence of the present section supports the conclusion that the type of cognitive ability most clearly measured by the Torrance battery is in fact the conventionally demarcated notion of convergent thinking or general intelligence, rather than a conceptually distinguishable domain for which the term "creative thinking" would be appropriate. Two other major kinds of evidence, however, are invoked by Torrance in further support of his argument that the Torrance instruments measure a characteristic that is suitably described as creativity—studies of evaluations by teachers or other judges and studies of evaluations by the subjects' peers. We shall consider each of these types of work in turn.

Evidence on Evaluations by Judges. Since we have demonstrated that the Torrance instruments coalesce strongly with the general intelligence domain, it will not be surprising to find that teachers or other judges can make cognitive evaluations that relate in some degree to scores on the Torrance tests. What would need to be demonstrated is that the evaluations in question are doing something more than essentially depicting contrasts along the general intelligence continuum. Evidence indicates, however, that even when explicitly instructed to do so, teachers or other judges find it difficult to evaluate elementary and high school students on bases that do not boil down to the familiar arena of convergent thinking. We shall first look at some general documentation of this point and then turn to studies involving the Torrance tests in particular.

In an extensive study of more than 1000 high school seniors who were National Merit Scholarship finalists, Holland (1959) obtained ratings by the students' teachers and principals for the trait of originality. Since National Merit Scholarship finalists will, after all, be a high intelligence group, the opportunity should be particularly present in such a case for judgments of originality to signify something other than the conventional intelligence concept. Yet the evidence clearly indicated that the judges could do little more with reliability in their originality ratings than discriminate individual differences in talent at convergent thinking. Not only did the originality ratings correlate highly with ratings for

such conventional characterizations as intellectual leadership, citizenship, maturity, achievement drive, and dependability, but the originality ratings also exhibited strong correlations with verbal aptitude scores and academic grades.

Similar results are found in work by Wallen and Stevenson (1960) on teacher judgments of the creativity of fifth graders' compositions. After practicing on an initial set of compositions, each of five teachers rated each of three compositions by over 60 fifth graders for creativity, with the concept defined in such terms as the following: "Creativity is the expression of information, ideas and feelings colored by original thoughts and inspired by the inner urge of an individual to express himself" (p. 274). The judges were explicitly instructed that spelling, neatness, vocabulary, and length were not to be considered, nor was poetry as such to be considered more creative than prose. With high agreement among judges and high consistency over stories for a pupil, the creativity ratings turned out to be strongly correlated (approximately 6 or 7) with measures of intellectual ability and academic achievement.

In yet other work along the same lines, Rivlin (1959) asked the teachers of students in the tenth and eleventh grades to study such criteria of creativity as "will venture into unfamiliar or new areas," and "demonstrates imaginative and original solutions to problems." The teachers then were to select from each of their classes five students who were not only intelligent but also creative, and five students who were equally intelligent but not creative. With over 100 high school students thus selected, the creative students were found to score significantly higher than the noncreatives on the Pintner measure of intelligence and on the Iowa Tests of Educational Development. Despite the request that they subjectively equate their creative and noncreative nominees for intelligence, therefore, the judges found it difficult to leave that domain out of the picture. Finally, we cite a study by Piers, Daniels, and Quackenbush (1960), where the correlation with intelligence of teacher ratings for creativity was less strong (.20), although still significant at the .05 level for the sample of 114. Here, however, rating agreement among the three

teachers who evaluated each student was found to be very low³

All in all, the findings that we have considered put the burden of proof on the investigator if he wishes to use evaluations by judges as evidence for the distinguishability of a creativity dimension from the more familiar concept of general intelligence. Rating reliability for "creativity" judgments seems to be found, by and large, to the degree that the basis for evaluation rests heavily upon the traditional convergent-thinking domain. In most of the research that has been conducted relating scores on the Torrance tests to putative creativity evaluations by judges, however, this crucial consideration has been ignored. Thus, for example, Torrance (1962, 1963), Torrance and Myers (1962), and Yamamoto (1963) have reported investigations in which teachers are asked to nominate pupils who are the highest and the lowest in the class with regard to fluency in production of ideas, flexibility concerning their ideas, originality in thinking, and ability to elaborate ideas. The classes in this work were at or above the fourth-grade level. The general finding is that significant relationships are obtained between teacher ratings in terms of one or another of the criteria just presented and the children's scores on the respective creativity variables from the Torrance tests. Hence there will be a relationship between ratings for fluency and test scores for fluency, between ratings for flexibility and test scores for flexibility, and so on. Such evidence then is cited in support of the construct validity of the Torrance measures (see, e.g., Torrance, 1966a). To do so ignores, however, our knowledge that the Torrance creativity variables tend to be intercorrelated, that ratings in terms of the criteria described tend to be intercorrelated—the well-known "halo-effect"

³ Ironically enough, the teacher ratings also were found to correlate with the originality measures that were used in this study, but not with the ideational fluency measures. As we recall from our earlier discussion of this research, however, it was the ideational fluency measures that were uncorrelated with intelligence, whereas the originality measures were correlated with intelligence. These further results reinforce the conclusion that the judges, when using their definition of creativity, in fact were evaluating intelligence.

phenomenon—and that the Torrance measures as well as the kinds of rating designation in question produce results that are substantially correlated with intelligence. These findings clearly can be accounted for in terms of intelligence differences as the common mediating variable: the teacher ratings predict the creativity indices to the extent that the ratings are judgments of general intelligence and the creativity indices share variance with intelligence.

Direct evidence on these points has been provided in a recent study by Lieberman (1965) with a sample of 93 kindergarten children. Utilizing two teachers as independent judges, ratings were obtained for five aspects of playfulness, defined respectively in terms of physical spontaneity, social spontaneity, cognitive spontaneity, manifest joy, and sense of humor. High interrater agreement was found in all cases. These five ratings, however, turned out to be strongly intercorrelated, indicating that a halo existed and hence only one characteristic in effect was being rated. Tasks for assessing ideational fluency, spontaneous flexibility, and originality were adapted from the work of Torrance and Guilford. The Peabody Picture Vocabulary Test served as the index of general intelligence. The findings were quite unequivocal: correlations between intelligence and the playfulness ratings were approximately .3 and significant, correlations between intelligence and the creativity variables were approximately .2 to .3 and significant, and correlations between the playfulness ratings and the creativity variables also were approximately .2 to .3 and significant. Clearly, the relationships of the ratings and of the creativity indicators to intelligence accounted for their relationship to one another. In view of this result, it is difficult to understand how Torrance (1966a) can cite the Lieberman study as an indication that evaluation by judges of creativity-relevant traits lends construct validity to his creativity assessors. Rather, the appropriate conclusion would seem to be that judgmental ratings fail to support the view that Torrance's measures tap a characteristic distinguishable from convergent thinking.

Evidence on Evaluations by the Subjects' Peers The situation with regard to peer evaluations seems to be similar to that regard-

ing evaluations by judges. Indeed, such an outcome should not surprise us, since if teachers or other judges find it difficult to evaluate a cognitive trait apart from general intelligence, such should be the case *a fortiori* for age-mates of the subjects. We present first a study that indicates the extent to which one can expect peer ratings for creativity to correlate with intelligence, and then turn to a study indicating findings obtained with Torrance's procedures.

In an investigation by Reid, King, and Wickwire (1959), seventh graders were asked to provide peer nominations in regard to creativity. Each pupil was requested to select three of his classmates who could be most appropriately described as having "good imaginations. They have new ideas and new ways of doing things" (p. 731). When peer nominations were carried out in these terms, the result amounted to very strong differentiation along conventional lines of academic aptitude and achievement. Nominated as more creative were the children who scored higher on such assessors as the California Test of Mental Maturity, the California Achievement Test, the Sequential Tests of Educational Progress, and mechanical and clerical ability tests as well.

Turning now to research relating peer ratings to the Torrance procedures, we fail to find information on general intelligence measures even though, as the Reid et al. study demonstrates, such information would be essential. Thus Yamamoto (1964b) carried out an extensive investigation of more than 400 students in grades 7 to 12. A battery of Torrance procedures was administered near the start of a term, and the students evaluated one another near the term's end by using judgmental criteria that were assumed to represent the types of creativity variable that were derived from the tests. Thus, for example, a fluency judgment was related to fluency scores on the creativity tests, a flexibility judgment to flexibility scores, and so on. Correlations for the entire group between the rating criteria and the test scores were on the order of the low 20s, and hence significant for this sample size. From the evidence already considered on relationships between cognitive ability ratings and intelligence, and on relationships between Torrance test scores and intelligence, it is evident that

the correlations here reported between the judgment criteria and the Torrance variables can be fully accounted for in terms of the extent to which relationships with general intelligence should be present. No information on intelligence was considered in the study. Thus the results are less likely to indicate that a creativity score for fluency correlates with sociometric nominations in terms of a fluency criterion, or that a creativity score for flexibility correlates with sociometric nominations in terms of a flexibility criterion, as Torrance (1966a) proposes, than to indicate that a halo effect is operating so that sociometric nominations by any criterion are tending to reflect general intelligence. The relationships between such nominations and the creativity scores then would be expected because the creativity scores are known to be reflective of general intelligence to a significant degree.

Neither evaluations by peers nor by judges, then, offer evidence for the distinguishability of Torrance's procedures from the convergent-thinking domain. While the major lines of findings regarding the grounds for construct validity of the Torrance instruments have now been reviewed, two further classes of studies involving these tasks will be described briefly: work on training effects and on age effects. Both kinds of research can be said to deal with the modifiability of scores on the Torrance tests as a function of experience.

Effects of Experience. A number of studies have been conducted where effects upon Torrance test performance of various kinds of training have been investigated. The general rule seems to be that enhanced performance can be obtained in this manner. Since, however, we have not been able to find satisfactory evidence indicating that the Torrance scores tap a trait that stands apart from the general domain of convergent-thinking skills, such training effects do not cast light on the construct validity issue.

In some of this research, the training procedures utilized were relatively similar to the Torrance tests themselves, so that what was provided amounted more or less to practice on the criterion. For example, Cartledge and Krauser (1963) provided groups of first graders with five 20-minute training sessions concerning how to improve toys to make

them more fun to play with. Not only was intensive instruction provided, but competition was encouraged as well. Various principles for improving toys were taught to the group. By using as pretest and posttest a product improvement task in which the subject was to think of ways to improve a toy dog, the experimental regime just described resulted in a greater score increase than did its absence. With the training involving such specific tutoring in the test skill, however, it would be surprising not to find an effect. Similar points apply regarding a comparable study by Torrance (1961a).

In other studies, while the training experience may be more distant from what is tested for on the creativity instrument, another factor seems free to operate—a factor which, incidentally, could well play a role in the Cartledge-Krauser study—enhanced confidence due to one or another form of greater attention by the teacher and greater acceptance of the individual's responses. For instance, Torrance (1966d) has described research using a battery of his verbal and figural tasks as both pretest and posttest material with approximately 1500 fourth graders. The pretest took place near the start, the posttest near the end of the school term, with the experimental classes receiving a complicated training regime as the treatment. Every 2 weeks a new unit of the materials developed by Cunningham and Torrance (1965) was administered to the classes. Each unit consisted of a recorded dramatization, of say, a great moment in scientific discovery such as the Wright Brothers' inventing of the airplane, exercises designed to serve as a stimulus for the kind of thinking illustrated on the record, and a teacher guide suggesting other related activities in which the teacher may lead the children. One would expect the intensive enrichment represented by such materials, with the greater amounts of attention which the teacher pays thereby to the students, to enhance the students' feelings of confidence and acceptance. The result should be a generalized training effect, so that enhanced performance would be found not just on the Torrance tests but on a range of other tasks as well. This is not to deny, of course, the social desirability of the enrichment here described, but rather to suggest its functional equivalence to other ways in which greater

attention to and acceptance of the pupils might also be provided, and to suggest the generality of the cognitive effects that most likely ensue.

Perhaps the most convincing training research yielding enhanced performance on the Torrance tests is that which has been carried out at the instigation of Crutchfield (see, e.g., Crutchfield and Covington, 1963, Crutchfield, 1964, Olton, 1966), where the materials were relatively distant in character from the Torrance tests and also were self-instructional in nature rather than requiring teacher intervention for their transmission. Fifth- and sixth-grade children who have gone through a series of self-instructional lessons concerning detective stories, which serve as vehicles for teaching certain problem-solving skills, have performed better on certain Torrance tasks than comparable children not so instructed. We have no clear grounds, however, for considering these effects to be evidence of increased creativity rather than of increased convergent-thinking skills.

Turning to research on age differences, the general finding has been an increase with age across the elementary and high school years in performance levels on the Torrance tests (e.g., Torrance, 1961b, Yamamoto, 1962, Lembright and Yamamoto, 1965). Such an increase would seem to reflect the cumulative impact of the various sources of information to which the child in our culture is exposed over time, and to be comparable to age-related increases that we would expect for this reason in other kinds of cognitive performance as well.

The Evidence in Retrospect In sum, we have not been able to find evidence suggesting that the Torrance instruments cohere among themselves to a degree greater than that to which they correlate with tests of convergent thinking. Nor have investigations concerning the threshold-of-intelligence hypothesis, evaluations by judges, and evaluations by peers, supported the construct validity of the Torrance battery. Given the promising leads that we obtained from research in the Guilford tradition, coupled with the general similarity between Torrance's materials and those of Guilford, why should work using the Torrance tasks lead us to such a disappointing verdict? We can suggest two major reasons.

Recall that our examination of the Guilford procedures suggested that the greatest independence from convergent thinking was found in the case of ideational fluency measures, with originality indicators also tending to exhibit independence from intelligence if they represented a kind of originality that should depend at least partly on the number of ideas emitted by the respondent. Flexibility measures, in turn, seemed to be more appropriately understood as within the convergent-thinking domain rather than as standing apart from it. We have found that the Torrance procedures are scored in terms of four variables: ideational fluency, originality of a kind that should indeed depend upon degree of fluency, spontaneous flexibility, and elaboration. The typical practice has been to construct as the creativity indicator an overall index score—hence a measure in which all four of these variables are reflected—whether restricted to verbal or visual procedures or representing a combination of both. We have already noted that spontaneous flexibility, however, seems to coalesce with general intelligence. Elaboration, in turn, seems on its face to be more appropriately construed as relevant to convergent than to divergent thinking, since it refers to a propensity for interpolating or filling in details. The upshot thus appears to be an index score in which two variables that seem relatively distinguishable from intelligence are confounded with two other variables that are not. An index score concerned only with ideational fluency and with fluency-related forms of originality would, in this view, exhibit considerably greater orthogonality from intelligence than an index score that is concerned with spontaneous flexibility and with elaboration as well.

Even if the prescription just set forth were followed, however, some degree of relationship with intelligence might still be found because of the administration context which surrounds the Torrance tasks. As we noted in considering the Guilford materials, the presence of relatively brief time limits and of a traditional aptitude or achievement testing situation with its evaluative connotations would not seem to be features conducive to the display of forms of thinking that depend upon generating new ideas. Thus some degree of relationship with traditional aptitude and

achievement tests may accrue simply as a result of shared method variance, that is, subjects who are proficient at following instructions in evaluational situations which set a premium upon speed should show up relatively well on the Torrance tests. Recent results by Boersma and O'Bryan (1968) in fact support this line of interpretation.

Getzels and Jackson

Theoretical Considerations In their research on students ranging from the sixth grade to the senior year of high school, Getzels and Jackson (1962) considered, as their basic means of contrasting the subjects, one or another IQ measure and a battery of five presumed creativity indicators. Of the five, one was derived from Guilford and three were original with the authors. What was the kind of cognitive excellence that they were expected to measure? Getzels and Jackson (1962) offer the following discussion of what they mean by creativity:

As it is used in this study, the term "creativity" refers to a fairly specific type of cognitive ability reflected in performance on a series of paper-and-pencil tests. Our tests of creativity involved the ability to deal inventively with verbal and numerical symbol systems and with object-space relations. What most of these tests had in common was that the score depended not on a single predetermined correct response as is most often the case with the common intelligence test, but on the number, novelty, and variety of adaptive responses to a given stimulus task (pp. 16-17).

In short, the authors mean to describe a single ability which their creativity instruments reflect in common—an ability that differs from intelligence along essentially the same lines as does Guilford's concept of divergent thinking. To the terms "number," "novelty," and "variety," as they appear in Getzels and Jackson's definition, we can, of course, coordinate the Guilford terms fluency, originality, and flexibility, respectively. We turn next to the five creativity instruments comprising the Getzels and Jackson battery: word association, uses for things, hidden shapes, fables, and make-up problems.

In the *word association* test, the subject is

presented with 25 words, each of which has multiple meanings—for example, bolt. His task is to set forth as many meanings as he can for each word. Thus “word association test” really is a misnomer. The task would more appropriately have been named the “word definition test.” With different meanings required by the instructions, what Guilford would call “adaptive flexibility” is at issue here.

The *uses* test requests the subject to write as many different uses as he can for each of five common objects that are named. Derived from Guilford, the procedure is, however, scored somewhat differently, in that measures of ideational fluency and of originality are combined into a single index: credits for number of responses are added to credits for number of statistically uncommon responses in arriving at a final score.⁴

Turning to the *hidden shapes* task, the respondent is shown, on each of a number of items, a simple geometric figure followed by four complex geometric figures, one of which contains the simple figure as a part. The subject is to choose the complex figure in which the simple figure is embedded. Cited to Cattell (1956), the authors justify its inclusion as a creativity assessor on the grounds that it appears to call for the ability to disregard superfluous detail and perceive essentials quickly in perceptual situations. Presumably, some kind of adaptive flexibility, to use Guilford's term again, would be at issue, in that the person must keep reorganizing his viewing of the complex figures until he finds the simple one.

For the *fables* test, each of several fables with a missing last line is presented, with the subject to supply three alternative endings to the fable—one moralistic, another humorous, and the third sad. The endings are scored in terms of whether they are sufficiently related to the rest of the story and whether they succeed in achieving the particular affective tone called for in a given instance—moralistic, funny, or sad. Something on the order of verbal sensitivity and of adaptive flexibility in shifting affective tone

⁴ Since, as noted earlier, this type of originality measure does seem to be strongly correlated with ideational fluency, construction of a single score reflecting uncommonness as well as total output is quite justified.

“upon demand” seem to be tapped in this procedure.

Finally, the *make-up problems* test offers the respondent various sets of numerical information from which he is to devise as many problems as he can. At issue here is the ability to sift carefully through the data offered as raw material for problem construction, and then to shift flexibly among alternative parts and arrangements of this material. A form of adaptive flexibility would again seem to represent at least part of what is tapped by this procedure.

As far as context of administration is concerned, the procedures just described were defined to the respondents as tests and administered to them in the fashion of academic examinations as they sat in their classrooms. That four of the five creativity tasks in the authors' battery seem to concern aspects of flexibility already must sensitize us to the issue of how distinguishable are these creativity assessors from convergent thinking, since, as we recall, our examination of the Guilford procedures suggested that measures of flexibility seemed to be part and parcel of the general intelligence domain. To what extent, then, does the present battery define a dimension that is separable from intelligence?

Relationships with Intelligence and Academic Achievement For the 292 boys in the Getzels and Jackson sample, all five of the creativity tests correlated beyond the .05 level with IQ, while four of the five did so for the 241 girls in the sample. Given such large samples, however, correlations might be relatively small and still significant, so that we must turn to the question of comparing the magnitude of correlations among the creativity tests with that between the creativity tests and the intelligence index. For the boys, the average correlation was .28 among the five creativity measures, but it was .26 between those measures and IQ. For the girls, the corresponding correlations were .32 and .27. Thus the only ability that the creativity assessors point to as what they jointly measure is the same kind of ability that is indexed by the IQ assessor. IQ was evaluated with different instruments and at different times for various members of this sample, with its extensive grade level spread from the upper elementary years to the end of high school, whereas the creativity battery

was administered at one point in time to the entire sample. It is not surprising therefore that the creativity tests would intercorrelate slightly more highly than their degree of correlation with IQ. Were a fresh IQ test to have been administered at the same time as the creativity battery, even this slight difference would, we suspect, have disappeared.

The general point just described has been made in a number of discussions of the Getzels and Jackson work—for example, by Burt (1962), Cronbach (1962), de Mille and Merrifield (1962), Faris (1962), Thorndike (1963b), Marsh (1964), and Wallach and Kogan (1965a). Furthermore, critics have noted that the correlations between the intelligence test and the creativity measures are artifactually depressed because age effects have been removed from the intelligence scores by using the IQ metric, but they have not been removed from the creativity scores.

From the initial sample of more than 500 students, Getzels and Jackson proceeded to concentrate on two very specific subgroups, one containing 26 and the other 28 subjects. "Creativity" was defined as the summation of the individual's performances on the five creativity tests—a practice which should result in a score that, like the IQ measure itself, can only constitute another estimate of general intelligence. The two groups were composed as follows. One, the "high creativity group," contained students scoring within the top 20% of their class and sex grouping on the creativity index but below the top 20% on IQ. The other, the "high intelligence group," contained subjects who scored within the top 20% of their class and sex grouping on the IQ measure but below the top 20% on the creativity index. Given a very high mean IQ—132—for the initial sample as a whole, what we have here are two groups that are both quite high in regard to convergent-thinking ability. Since most of the creativity tests were, at least, not *intended* to measure general intelligence,⁵ and since their degree of internal coherence is not strong, the index score that reflects the variance they have in common probably represents a more imperfect

estimate of the convergent-thinking domain than does the IQ score. The IQ was, after all, explicitly fashioned as an intelligence measure, and its component parts are known to have high internal coherence. With the IQ score and the creativity battery functioning therefore as a somewhat better and a somewhat poorer estimate, respectively, of general intelligence, the high creativity group consists of students who have scored a little higher on the poorer intelligence index than they have on the better intelligence index, whereas the high intelligence group is composed of students who have scored a bit higher on the better intelligence index than they have on the poorer intelligence index. The clearest inference one can draw is that the two groups are of comparably high intelligence and not shown by these tests to be different in any other respect. The only further inference that may be valid is that the "real" intelligence level of the high creativity group may—although still high—be lower than that of the high intelligence group, given their relative standings on the poorer and better intelligence indices. It should also be the case, of course, that the group comprised of persons in the top 20% by both criteria should be the most intelligent of all—since, in their case, the two intelligence probes are in full agreement. The authors did not study, however, this last-named group.

If the two groups studied are comparably high on intelligence, and if the creativity index score provides no information with any reliability other than a second estimate of intelligence, then we are left with two groups that are similar rather than different in the authors' fields of interest. If the two groups are found to differ on some other measure, it could be for any number of reasons stemming from the vagaries of sampling, but it cannot be because of a "creativity versus intelligence" contrast. To mention just one of the myriad accidental contrasts that could have arisen between the groups, Cronbach (1962) notes that the "age distributions of the two groups are not reported and perhaps differ" (p. 279). The differences that are reported by Getzels and Jackson between their high creative and high intelligence groups therefore cannot be taken seriously because we cannot know why they arise. The similarities that are found between the groups, on the

⁵ Ironically, the hidden shapes test actually *has* been used in connection with intelligence assessment. For a discussion and some findings, see, e.g., Witkin, Dyk, Faterson, Goodenough, and Karp (1962).

other hand, can be readily understood on the ground that the two groups are comparable in general intelligence

Perhaps the major similarity to which the authors call attention is in regard to scholastic achievement. Both the high creative and the high intelligence groups were found to exceed the general sample average regarding school achievement as measured by standardized achievement tests. Since the two groups are of comparably high intelligence, however, and since we know that achievement and aptitude indicators are strongly correlated, we could hardly expect otherwise. What the authors quite inappropriately conclude from this finding, on the other hand, is that high creative students achieve just as well in school as do high intelligence students.

Before reviewing several studies that have used a set of procedures similar to the Getzels and Jackson battery, it is of interest to dissect the authors' battery into its five constituent measures and consider whether their separate relationships with intelligence and academic achievement vary in a manner that we can predict from evidence examined earlier. According to our description of the tasks, four—word association, hidden shapes, fables, and make-up problems—seem to tap aspects of Guilford's adaptive flexibility concept, whereas one—uses for things—represented a combination of ideational fluency and the type of originality index that should covary with such fluency. If we recall our earlier analysis of studies using the Guilford procedures, flexibility measures turned out to be indistinguishable from the convergent-thinking domain, while ideational fluency and the type of originality score that would be dependent upon high ideational output seemed to be maximally distinguishable from convergent thinking. This immediately leads to the hypothesis that the failure of the Getzels and Jackson battery to gain separability from intelligence arises because the majority of its component tests reflect aspects of flexibility. On this interpretation, the uses measure should have a lower correlation with IQ and with scholastic achievement than the other four creativity tasks.

From the relevant data in the Getzels and Jackson book, this hypothesis receives some support. Of all five creativity measures, the uses task has the lowest correlation with ver-

bal scholastic achievement for males and for females, the next to lowest correlation with numerical scholastic achievement for each sex, and the next to lowest correlation with IQ for each sex.⁶ To give some magnitudes, uses correlates .19 with verbal achievement for males, whereas the average correlation of the other four creativity tasks with verbal achievement for males is .44. For females, the corresponding correlations are .23 and .47. Turning to numerical achievement for the males, uses correlates .21, while the average r for the other tasks is .29. In the case of the females, .24 and .31 are the corresponding correlations. Regarding IQ, for the males, uses correlates .19, with an average r for the other tasks of .28. For the females on IQ, the corresponding r values are .15 and .30. The other four creativity tasks by the way show an average intercorrelation of .31 for the males and .35 for the females, thus indicating somewhat greater cohesiveness as well as a stronger correlation with IQ when uses is left out of the battery. In sum, although the Getzels and Jackson creativity battery as a whole cannot be separated from the convergent-thinking domain, the only one of its five parts that taps ideational fluency and a fluency-related form of originality does seem to be more distinguishable in this regard. Viewed in relation to the achievement question, what this means, of course, is that to the extent that one finds a creativity measure that does look relatively distinguishable from intelligence, it also will turn out to be relatively unrelated to academic achievement.

In closing this section, we consider three investigations that used a range of procedures closely resembling the Getzels and Jackson creativity battery, although none was identical to it. Ripple and May (1962) found, not surprisingly, that correlations between IQ and creativity task scores will be higher when IQ variability in the sample is greater. They compared samples of seventh graders that were more homogeneous versus more heterogeneous in IQ. Detailed inspection of their results, however, yields a very intriguing further out-

⁶ The three tasks that uniformly show the highest correlations with IQ, with verbal achievement, and with numerical achievement—ranging, indeed, into the .50s—are word association, hidden shapes, and make-up problems, all of which have an evident dependence on adaptive flexibility.

come. If we consider their sample that was maximally heterogeneous in IQ—the sample where correlations of IQ with creativity scores were highest—six of the nine creativity measures had correlations with IQ significant beyond the .01 level. Of the remaining three measures, two were unrelated with IQ, whereas the third just passed the .05 level in its degree of relationship. What these three measures had in common was that they all concerned aspects of ideational fluency.

With 110 sixth graders as subjects, Flescher (1963) derived a presumed creativity index from summing the standardized scores on seven procedures, which, if anything, were even broader and more heterogeneous in content range than the Getzels and Jackson battery. Although the average correlation between the creativity measures and IQ scores from the California Test of Mental Maturity was only .04, the average correlation among the creativity scores themselves was a mere .11. The creativity measures thus had little in common with IQ, while they also had little in common with each other. Clearly, there was no warrant for the summing of these creativity measures into a single overall index.

An extensive replication of the Getzels and Jackson work was recently reported by Hasan and Butcher (1966). The subjects were 175 male and female students in their second year of high school, to whom were administered 10 creativity instruments that included all the tasks from the Getzels and Jackson battery except the hidden shapes test. Standard measures of intelligence, verbal achievement, and numerical achievement also were obtained. The results strikingly confirmed our conclusions from the Getzels and Jackson research: the type of creativity battery in question yields essentially the same overall orderings of individuals as provided by measures of intelligence or achievement. If anything, the creativity scores correlated even more strongly with intelligence than they did among themselves. For the total sample, the average correlation of the 10 creativity measures with intelligence was .42, while the average correlation among the creativity indicators themselves was .25. The creativity composite score, intelligence score, verbal achievement index, and numerical achievement index all intercorrelated with sufficient strength—in the 60s, 70s, and 80s—to indicate that they clearly

were functioning as alternative measures of the same dimension. Thus, for example, the correlation between the creativity composite and intelligence was .74.

Hasan and Butcher point out, furthermore, that their sample actually was less variable on intelligence than was the Getzels and Jackson sample. Despite this reduced spread of IQ scores, the results once again indicated that the only characteristic which the kind of creativity battery under consideration can measure with any reliability is none other than general intelligence.

Evidence on Teacher Preferences. Apart from the claim that the high creative and the high intelligence groups both show superior academic achievement, perhaps the other best-known assertion that Getzels and Jackson have made is that, in terms of which students the teacher most enjoys and most prefers to have in class, “teachers give better ratings to the high IQ students than to the high creativity students” (1962, p. 32). We shall explore the evidence for this assertion at some length because a replication study by other investigators has included the key comparison group omitted by Getzels and Jackson—students in the upper 20% on both IQ and creativity.

In the Getzels-Jackson study, teachers were asked to evaluate their students by a criterion that emphasized personal liking: the degree to which they preferred having the student in their class. Compared were the high intelligence group, the high creative group, and the remainder of the total sample in the research. The high intelligence group was found to earn significantly higher teacher preference ratings than the remainder of the sample. The high creativity group, in turn, earned teacher preference ratings that also were higher than those for the remainder, but not significantly so. From these findings, the authors conclude that while the “high IQ group stands out as being more desirable than the average student, the high creativity group does not” (1962, p. 30). They quickly lapse, furthermore, into a language which directly compares the two groups, referring in subsequent pages to the high intelligence group as preferred by the teachers over the high creative group.

What do these findings really show? As de Mille and Merrifield (1962) and Wallach and

Kogan (1965a) note, the high intelligence and high creative groups actually do not differ significantly from each other regarding teacher preferences. At best one comes away with the suggestion that the two groups may both be somewhat preferred by their teachers to the remainder of the sample, with the evidence a bit clearer in the case of the high intelligence group. But now we must return to the question of what these groups mean psychologically. As we discussed earlier in considering how the groups were constituted, all we can know is that the two groups are of somewhat superior intelligence, with the further possibility that the high intelligence group exceeds the high creativity group regarding intelligence. We hence find complete correspondence between the ordering of the samples in terms of intelligence and in terms of teacher preferences: values on both dimensions are highest for the high intelligence group, lower for the high creativity group, and still lower for the remainder of the sample.

With the creativity composite as well as the IQ measure both providing estimates of general intelligence, we should expect, of course, that the highest teacher preferences of all would be awarded to the students who score within the top 20% by both measures. In this case, as we noted earlier, the two estimates of intelligence agree in placing the student very high on the continuum. Although Getzels and Jackson report no data on such a group, it has been studied in relation to the teacher preference issue by Hasan and Butcher (1966). These authors replicated Getzels and Jackson's findings of stronger teacher preferences for the high intelligence group than the high creativity group, but they found further that the strongest teacher preferences were awarded to the group high on both measures. As implied by our interpretation, then, the results indicate that teacher preferences are maximal for the group high by both criteria, lower for the group high by the IQ measure but not correspondingly high by the creativity index, and lower still for the group high by the creativity index but not correspondingly high by the IQ measure. Hasan and Butcher's evidence thus supports the view that all the creativity score provides is another estimate of general intelligence, and a poorer one at that.

It might be noted that the present material on jointly predicting teacher preferences from

an intelligence measure and the Getzels-Jackson type of creativity index is quite analogous in outcome to the work discussed in connection with Torrance on jointly predicting academic achievement from an intelligence measure and the Torrance type of creativity index. In both cases, the IQ score carries the major predictive burden, with addition of the creativity index increasing predictability by about the margin one would expect if that index were functioning as an ancillary estimate of intelligence. In neither case is the purported creativity index doing work that would not be equally well, and perhaps even better, performed by administering a second intelligence test.

Other differences reported in the Getzels-Jackson research program between their high creative and high intelligence groups (see, e.g., Getzels and Jackson, 1960, 1962) are uninterpretable because, as already discussed, responsibility for the differences may rest upon any number of accidental ways in which the two groups are distinguished, and does not in any case rest upon a creativity-intelligence contrast. Since the crucial comparison information on the "high-high" group is never considered, we can gain no clues as to what really may be at issue psychologically. One further study in that program, where a different mode of analysis was employed, gives some instructive findings. Jackson, Getzels, and Xydis (1960) correlated each of the five creativity measures separately with an index presumed to tap "nonpathological fantasy" on a group-administered Rorschach test. The subjects were the ones already described in our consideration of the Getzels-Jackson book, with results examined in the present case for the total sample of 292 males and 241 females. As the Rorschach measure, each of four Rorschach cards was projected on a screen, with the subject to choose from ten multiple-choice responses the three that he considered most appropriate to the picture. Included among each set of ten responses were four considered to be "pathological," most of which involved references to violent aggression, such as "bloody clouds" or "bloody stomach." The smaller the number of such responses included among the subject's choices, the higher his score for nonpathological fantasy.

Given the character of the measure just described, it would seem that something on

the order of sensitivity to or interest in making the more socially appropriate selections is at issue here. The measure in question did not correlate with any of the five creativity scores for the boys. In the case of the girls, however, it correlated with three of those creativity scores—the word association test, the hidden shapes test, and the make-up problems test. It will be recalled that these are the very same three creativity tasks that were found to possess the strongest correlations with IQ, verbal achievement, and numerical achievement. And, indeed, the Rorschach measure under consideration is also found to correlate with the females' IQ, verbal achievement, and numerical achievement scores. The positive results obtained for the girls therefore would seem to mean not that creative individuals are more given to nonpathological Rorschach fantasy, but rather that intelligent individuals are more likely to make socially appropriate choices on the Rorschach task.

As an example of the confusion that has been sown among others by the Getzels and Jackson research, consider finally a report by Smith and White (1965). In using the Getzels-Jackson word association procedure as their measure of creativity, a significant correlation (.17) was observed in a sample of 156 young male adults between creativity and a sociometric choice indicator of how witty and amusing the person seems to his peers. Since the word association task in question has been found to measure nothing apart from convergent-thinking ability, what the present finding would seem to indicate is that, not surprisingly, the more intelligent subjects seem more witty to their peers. The authors, however, view their results as suggesting that witiness is an attribute of the creative person.

The Evidence in Retrospect As in the case of the Torrance procedures, for the creativity assessment battery developed by Getzels and Jackson we have not found evidence of greater coherence among the tasks in question than the degree to which they correlate with measures of intelligence. The composite score presumed by Getzels and Jackson to reflect a form of cognitive excellence separable from intelligence and appropriately described with the term "creativity" has turned out, rather, to constitute a second—and less reliable—measure of general intelligence. The high intelligence and high creative groups defined

and contrasted by the authors have been found to reflect no intelligence-creativity contrast, but rather to consist in both instances of high intelligence students, with the former group likely to be of somewhat higher intelligence than the latter, and with the two groups differing otherwise in accidental ways. In regard to teacher preferences, it is not the case that—as the authors propose—teachers prefer the high intelligence group over the high creative group, but rather that—as we would already suspect from our earlier review of evidence on evaluations by judges—teacher preference is correlated with general intelligence level.

Our internal analysis of the Getzels-Jackson creativity battery has suggested that an important reason for its failure to yield a measure separable from convergent thinking resides in the battery's emphasis upon assessors of what Guilford would call adaptive flexibility. Of the five tasks in the creativity battery, the three that showed the strongest relationships with intellectual aptitude and achievement measures concern a person's ability to give alternative definitions for words, to perceive alternative structures in visual patterns, and to use alternative parts and arrangements of descriptive material in constructing problems. All of our evidence points, however, to the conclusion that set-shifting ability of this type characterizes the high intelligence individual, and thus cannot be separated from the convergent thinking domain. The one task in the battery that reflects ideational fluency and a fluency-dependent kind of rarity or uniqueness of ideas, on the other hand, showed only weak relationships with convergent thinking assessors, thus confirming earlier indications that the characteristics in question may well be distinguishable from intelligence. Since the present work, moreover, once again utilized an assessment context characterized by evaluational stress and time pressure, the degree to which ideational fluency and fluency-related forms of originality are independent of traditional forms of intelligence may well have been underestimated.

A Look Ahead From all of the research reviewed to this point in the chapter, we can distill a major positive conclusion. There does indeed seem to be a kind of cognitive excellence that both is empirically distinguishable from convergent thinking and also possesses

some face validity in connection with the "creativity" term. However, it is much more specific and restricted in character than has been assumed by the investigators considered thus far. The type of cognitive talent in question seems to concern a person's ability to produce a large number of ideas in response to a given task constraint, where the ideational content that is generated is reasonably appropriate to the task at hand and, at least partly by virtue of its quantity, includes a goodly amount of content that is relatively unique or unusual. Procedures reflective of such ideational fluency and of forms of originality that seem dependent upon an extensive flow of ideas have been found to be maximally orthogonal to intelligence. That the ideational content at issue here remains relatively appropriate to the given task rather than ranging into the bizarre can be asserted for a simple reason. Appropriateness has constituted an implicit part of the task instructions, and most of the studies have been conducted with subjects who, either by virtue of membership in the middle class or by virtue of their involvement in a social system with authoritarian overtones—such as the classroom or the military—can be expected to conform reasonably well to the demands set by the experimenter.

Our concern with isolating thinking processes that may be described as creative without doing violence to the term thus has led us to consider what may be called associative fluency and uniqueness: the flow of ideas and the uniqueness of their content. Notice that we use the term "association" in a different sense from that which Getzels and Jackson implied when they designed their word association test, where performance depended upon a person's flexibility in coming up with diverse meanings for a given word. We are referring not to flexibility in shifting from one cognitive category to another, but to fluency in generating cognitive units whatever their category membership. Such fluency is, indeed, considerably more associative in character than the ability to shift set, where a heavy emphasis must be placed upon evaluating whether, for instance, the second definition one offers for a word is sufficiently different from the first. As a matter of fact, it may well be this necessarily heavy emphasis upon evaluational processes—as distinct from the business of generating ideational possibil-

ities as such—that leaves measures of flexibility closely united with convergent-thinking ability (see Wallach, 1967). What may be at the psychological root of associative fluency and uniqueness therefore is one's disposition to produce ideational possibilities under circumstances where evaluational activities are at a minimum. One is referring here to a person's disposition to "ride associative currents," as it were.

Wairant can in fact be found in the introspections of undeniably creative artists, musicians, writers, scientists, and mathematicians, for emphasizing the riding of associative currents when one seeks to formulate a definition of creativity in thinking processes. A volume edited by Ghiselin (1955) contains many relevant quotations along these lines, as does a volume edited by Hadamard (1945). To offer just two examples, Einstein refers to the need for "combinatory play" and "associative play" regarding images and ideas (Ghiselin, 1955, p. 43), and Dryden notes that his writing activities involve the generating of "a confus'd Mass of Thoughts, tumbling over one another in the Dark" (Ghiselin, 1955, p. 80). Implicit in such introspective accounts are a temporary suspension of evaluational processes and an obtaining of innovative possibilities by means of the very abundance of ideational output. Analogous points have been made by McKellar (1957) and by Rugg (1963). Associative fluency and uniqueness as the core of a process definition of creativity thus can be said to possess a modicum of face validity—at least if one accepts such introspections as reasonably veridical.

Work that concentrates on associative processes, then, may move us closer to an understanding of creativity in thinking, and it is to such work that we turn in the sections that follow.

RESTRICTING THE DEFINITION TO ASSOCIATIVE PROCESSES

Three major lines of research can be delineated whose operational approach has concentrated on associative processes: work by Maltzman and others who have dealt with training in the giving of original associative responses, studies oriented around Mednick's Remote Associates Test, and work by Wallach and Kogan. We shall take up these research

paths in their order of historical emergence, turning first to studies on the training of associative originality

Maltzman and the Training of Associative Uniqueness

Maltzman provided the stimulus for many researchers' efforts to enhance the level of uniqueness of a person's associations when confronted with a particular task request through experimental manipulations that encourage subjects to give unique responses to stimuli. What these training regimes seem oriented toward is the establishment of an attitude on the subject's part conducive to his entertaining diverse associative possibilities in response to a given stimulus—and hence the entertaining of possibilities that are more unique or remote. Thus Maltzman and his collaborators (Maltzman, Bogartz, and Breger, 1958, Maltzman, Brooks, Bogartz, and Summers, 1958, Maltzman, 1960, Maltzman, Simon, Raskin, and Licht, 1960, Maltzman, Belloni, and Fishbein, 1964) were interested in facilitating "original thinking," which they defined as "behavior that occurs relatively infrequently, is uncommon under given conditions, and is relevant to those conditions" (Maltzman et al., 1960, p. 1). In one experiment, Maltzman, Bogartz, and Breger (1958) found that repeated evocation of different associative responses to the same stimuli in a free association task led the undergraduate subjects to provide associative responses of greater uniqueness when offering free associations to a list of stimulus words different from that on which training had occurred. Evidence of transfer from such training to the production of unique uses on Guilford's unusual uses test, however, was equivocal. A more extensive examination of this issue in a subsequent study (Maltzman et al., 1960), on the other hand, found clear evidence of transfer to uniqueness of ideational content on the unusual uses test as well.

Let us consider the latter investigation in greater detail. In all conditions, the experiment began by presenting the undergraduate subjects with a list of 25 stimulus words, for each of which they were to respond with the first word that came to mind. The training regime then presented the subjects with five successive repetitions of this list, requesting that they give a different associative response

than the one used before when a word came up on each successive repetition. The individual thus was forced to search his repertoire for relatively remote associates of a given word. The number of statistically unique uses provided on the unusual uses task was significantly greater after this experience than after various control regimes administered to other subjects, such as giving the same associative response to a particular word when it came up on each of five repetitions of the list, giving an associative response to each of 125 different common stimulus words, giving an associative response to each of 125 different uncommon stimulus words, reading different unique associates on five successive repetitions of the original list of 25 words, or simply having no special training at all. Indeed, the experience of providing the same associate in response to a given word when it occurred on each of its five repetitions was found to eventuate in significantly less productivity of unique uses on the unusual uses task than was the case for the other control conditions.

These findings are by no means obvious, since a sizable conceptual gap intervenes between a task in which the subject responds with an association that occurs to him when presented with a particular word and a task in which the subject describes as many uses as possible for a given object, with the implication that the uses must be of relevance rather than bizarre. What the results suggest is that productivity with respect to unique uses is influenced by experiences that orient the subject toward or away from the utilization of lower likelihood associates of a stimulus. Maximum generation of unique uses is found to follow a situation in which the subject was urged to seek out lower likelihood associates to a stimulus word and to forswear the common associates, minimum generation of unique uses, on the other hand, is found to follow a situation in which the subject was urged to concentrate his attention on the most likely associate of the stimulus word. One can think of these instructions as influencing the likelihood of emission of more and less probable associates in response to a stimulus. The "lower likelihood" instruction reduces the likelihood of responding with common associates and increases the likelihood of responding with uncommon associates,

whereas the "most likely" instruction increases the probability of making common associative responses and reduces the probability of making uncommon associative responses. We know that in general there will be a falling gradient of probability levels for responses to a given stimulus as the responses become decreasingly common associates of that stimulus (see, e.g., Maltzman, Bogartz, and Biege, 1958, Maltzman et al., 1960). With decreasing commonness of response therefore the gradient of response probability starts lower and falls off more gradually as a result of the former instructional regime, whereas it starts higher and falls off more steeply as a result of the latter.

All that the preceding formulation does, of course, is describe the effect of the contrasting instructional conditions upon the likelihood of emitting associative responses of greater and lesser commonness when presented with a stimulus word. That a flattened gradient does in fact emerge from encouragement to give different associates upon subsequent repetitions of a stimulus word is evidenced by Maltzman et al.'s (1960) finding that as the word list receives more repetitions under the instruction in question, the percentage of fully unique associative responses offered by the sample keeps rising—from approximately 10% on the first repetition to approximately 70% on the fifth. What is of particular note, however, is that the present experiment's instructional manipulation of the shallowness or steepness of the probability gradient for making common and uncommon associative responses transfers to influence whether or not the subject comes up with unique uses when subsequently confronted with the unusual uses task. Flatness or steepness of associative gradient thus has been found to be a germane concept for interpreting unusual uses performance.

To argue that the transfer effects regarding uses performance result from manipulations of the subjects' associative gradients depends, of course, not only on the findings for the two conditions that, respectively, maximized and minimized such transfer, but also on the findings for the remaining conditions, where uses performance was uniformly intermediate. The latter conditions, it will be recalled—all of which yielded the same results—included the giving of an associative response to each of a

variety of stimuli, the reading of a variety of unique associates to a given stimulus, and the absence of training altogether. Thus for training to cause positive transfer, the subject had to generate a multitude of associates to a given stimulus, insuring thereby that relatively uncommon associates to that stimulus would result, and the subject had to search his own head for the associates rather than engage in mere observation of unique associates served up by another.⁷ The first point means that a flattened gradient had to be produced, the second means that the gradient concept refers to the effects of an active process of generating associates.

In a recent study with undergraduates, Sieber and Lanzetta (1966) investigated another effect of the flattening of associative gradients in response to a stimulus—the implication that a person who is permitted only one task response will be more indecisive in choosing the response to offer if he has been trained in the use of flatter gradients. This outcome was in fact obtained. Whereas the Maltzman group found the flattening of associative gradients to induce greater productivity of unique ideational content, Sieber and Lanzetta have found the flattening of associative gradients to result in greater indecisiveness because of conflict among alternative possible responses. An experiment also has been carried out which provides a direct demonstration of the congruence implied by the aforementioned work between such indecisiveness and the generation of original responses. We would expect, in other words, that if it is appropriate to view the Maltzman et al. and Sieber-Lanzetta lines of work as both concerned with the slope of associative gradients for responses to a stimulus, then indecisiveness among alternative possibilities, as measured in one situation, should be correlated with productivity of unusual ideational associates, as measured in another. In confirmation of this expectation, Worell and Worell (1965) found, with undergraduate subjects, that persons who displayed more indecisiveness in describing aspects of their behavior also exhibited greater uncommonness in the responses they gave to each of a number of stimuli on a word association test. There is a convergence of evidence,

⁷ A similar finding has been reported by Freedman (1965).

then, supporting the view that the relative originality or unusualness of the ideational content produced in response to one or another kind of task requirement may be usefully conceptualized in terms of the relative flatness of a person's associative gradient

Although it is clear that experimental induction of flattened associative gradients results in the enhanced production of unique ideas in a given task setting, it is not clear how successful this kind of training will be when the criterion concerns enhanced availability of one particular unusual associate that is defined in advance by the experimenter. Since the latter criterion is much more strict and specific than the former, it is perhaps not surprising that the results would be more equivocal. Thus training in the entertaining of uncommon ideas in response to a given task stimulus was not found to facilitate problem-solving that depended on producing a particular idea that was unusual relative to its context in studies by Anderson and Anderson (1963) with sixth graders, Caron, Ungei, and Parloff (1963) with high school students, and Maltzman, Belloni, and Fishbein (1964) with undergraduates. On the other hand, at least partial evidence for this kind of highly specific facilitation as a function of such training was found in studies by Flavell, Cooper, and Loiselle (1958), Maltzman, Brooks, Bogatz, and Summeis (1958), Freedman (1965), and Yonge (1966), all conducted with college students. That any positive instances can be located of this kind of facilitation is, of course, quite noteworthy, since various extenuating factors can always account for the negative instances.

To take an example from each group of investigations, consider first the report by Anderson and Anderson (1963). Sixth-grade boys were trained to generate unusual uses for familiar objects through group tutoring sessions in which the experimenter would direct the subject's attention to various properties of a given object and would provide encouragement for offering uncommon usage possibilities. Such training transferred to the production of larger numbers of novel uses for familiar objects that had not been included in the training series, but not to the solution of problems which required that a familiar object be used in one specific unusual way in order for success to be attained.

On the other side of the ledger, consider Yonge's (1966) research. With female undergraduate subjects, the solution of interest to the experimenter in a criterion problem required that an electrical switch be given the uncommon function of serving as a weight to be attached to a string so as to form a pendulum.⁸ Prior experience utilizing the switch in its customary role as part of an electrical circuit makes it difficult to ascribe to the switch the required use of functioning as a weight. Such negative transfer was overcome, however, in the case of subjects who received prior experience not only with the common function but also with the use of the switch in a variety of uncommon functions—for example, as a straightedge ruler when drawing a design and as a holder for a piece of cardboard—as long as experience with the common function did not precede experience with all the uncommon functions. Involvement in tasks requiring that the switch function in unusual ways thus was found, under certain circumstances, to facilitate solving a problem by using the switch in a particular unusual way that had not been experienced before.

In this section of the chapter, we have brought together some work that bears upon the psychological underpinnings of the unusual uses procedure. It is productivity and uniqueness of ideational content on tasks of this kind, we recall, that were found in earlier sections to define a form of cognitive activity that is maximally independent of convergent thinking. Given the evidence that we have considered regarding how to enhance performance experimentally on the present type of task, it has proven useful to conceive of the person who is able to suggest numerous unusual uses for an object as possessing a flattened associative gradient relative to the person who can suggest only few such uses.

A step has been made, then, toward our understanding the cognitive difference between the person who can suggest many possible—and therefore also many that range into unusual and remote ideas—uses for an object, or consequences of some event, or

⁸ The problem—adopted from Maier (1931)—requires the subject to grasp two strings suspended from the ceiling at a greater separation than his arms can span, which he can do if he swings one string with the switch attached as a weight.

problems suggested by certain common situations, or titles for a story plot and the person who can suggest but few. To view this difference in terms of shallow versus steep associative gradients is, of course, only to provide a descriptive model for what we have observed, but one, nevertheless, which seems to possess a fair amount of summary power. The next step is to ask why some people seem to bring flatter associative gradients than others to the cognitive tasks that confront them. In the following part of the chapter, we turn to a line of research from which we can begin to glimpse an answer to this question.

Mednick and the Role of Attention

Deployment in the Remote Associates Test

Theoretical Considerations The starting point for Mednick's approach to creativity is the associative gradient concept to which we were led in our preceding discussion. By basing his view upon the kind of introspective accounts cited earlier, where we noted that outstanding contributors to the arts and sciences emphasized the importance of generating abundant quantities of associative content in arriving at novel principles and products, Mednick (1962) proposed that the creative thinker will be characterized by a relatively flat rather than steep gradient regarding the likelihoods with which different associates will occur to him as he contemplates a task. Given an associative gradient whose downward slope is more gentle, the creative individual will be less fixated upon the common associations to an idea and more capable of reaching the distant, inaccessible associations⁹—those which, in relation to the initial idea, constitute "new combinations which either meet specified requirements or are in some way useful" (p. 221).

How does Mednick measure creativity? Rather than assessing associative productivity and uniqueness directly, he chose to deal with a by-product of the number and uniqueness of the associates that a person is capable of generating: the person's ability to produce a particular associate that is related on a purely associative basis to each of three words with which he is presented. The likelihood of solv-

ing this kind of associative problem should depend upon how numerous—and therefore also how unusual—are the associates that the person produces in response to the three words that are offered. The greater this productivity, the easier it will be for the person to hit upon the word that provides an associative "mediating link" to the other three. To give some examples from Mednick's (1962) measuring instrument—the Remote Associates Test (RAT)—one item consists of the words rat, blue, and cottage, while another item presents the words go, poke, and molasses. For still other items the word triads are sixteen, heart, cookies, surprise, line, birthday, and railroad, girl, class. The respective answers for the five items that have been presented are cheese, slow, sweet, party, and working. By comparing each answer with the triad that is to elicit it, we can see that the items have been constructed in such a manner that the mediating link in all cases is "strictly associative rather than being of a sort that follows elaborate rules of logic, concept formation, or problem solving" (Mednick, 1962, p. 227).

Although the RAT typically is administered as a test with a time limit, the timing is quite lenient—40 minutes for 30 items—so that time pressure should be minimal. However, the fact remains that Mednick's own formulation would seem to imply rather that the procedure be administered without any time limit at all. Some individuals who would otherwise be able to better their scores may be prevented from doing so by even the lenient time limit adopted. Since the RAT is a procedure with a correct answer specified in advance for each item, it has of course in this regard the look of a test of convergent rather than of divergent thinking. Given the dependence of the RAT upon strictly associative processes for solution, however, its resemblance to tests of convergent thinking is only superficial. A potential problem caused by this format nevertheless is that the experimenter's creativity in composing test items limits the degree of creativity that a subject can display. The consequence is that the instrument therefore may not be as sensitive in its upper range as would otherwise be the case. For most purposes this issue would not seem to be a serious one.

The clearest retort to these procedural

⁹ Emphasis upon the importance of variation among the cognitive elements that are available for use also is present in Campbell's (1960) analysis of creative thinking.

questions, however, consists of demonstrating, as Mednick's formulation implies, that productivity and uniqueness of content in generating associates are related to RAT performance. A number of studies have shown this to be the case.

The Bridge from Associative Productivity and Uniqueness to Remote Associates Test Performance Two kinds of research can be cited to document the assertion that associative productivity and uniqueness, on the one hand, and RAT performance, on the other, constitute equivalent operations: manipulatory and individual difference investigations. Turning to manipulation research first, Freedman (1965) contrasted the effects of three kinds of experience upon subsequently measured RAT performance levels: generating associations to stimulus words, reading the associations produced by others to stimulus words, and defining stimulus words. In more detail, the subjects in the first condition were to associate freely to each of 10 words, with encouragement to respond with whatever words came to mind. Every subject in the second condition was paired with a subject in the first condition, receiving for each word a card to be read containing the associations that the other person had offered for that stimulus. Subjects in the third condition were to provide a definition of each of the same stimulus words used in the other conditions. Neither the stimulus words nor any of their common associates were the answers to any of the RAT items. For all of the undergraduates in the study, the experience prior to taking the RAT was described as a brief warm-up exercise. The results indicated that significantly higher RAT scores were earned by subjects in the first condition than by subjects in either of the other two conditions, which in turn yielded similar RAT levels. Generation of plentiful associates—and hence also of relatively uncommon ones—thus was found to facilitate RAT performance. That passive reading of associates produced by others was not sufficient to facilitate RAT performance indicated that the generating process itself, and not just its cognitive consequences, had to be present. That the providing of definitions for the stimulus words also failed to facilitate RAT performance indicated that the generating process at issue

had to be strictly associative in character.

Whereas the results of the Freedman study were quite clear-cut, an earlier related experiment by Caron, Unger, and Parloff (1963) had failed to obtain facilitation of RAT performance from an associative training condition. Freedman (1965) has pointed out, however, that greater remoteness from the stimulus word most likely was attained in his association condition rather than in that of Caron et al. Unlike the Caron et al. procedure, where the stimulus word was repeated each time a new associate to it was requested, Freedman presented the stimulus word only once, with all of the subject's associations to it then following. The Caron method should keep the associates more closely linked to the stimulus than the Freedman technique, and hence the latter should result in flatter gradients—that is, in the production of associates of greater uniqueness or remoteness relative to the stimulus.¹⁰

Turning next to individual differences research, Mednick (1962), for example, has reported a correlation of .38 between associative productivity and RAT scores for a sample of 38 college students. The association task, not unlike Freedman's, requested the subjects to write as many associates as they could to each of 20 words, with 1 minute per word.

In a study by Mednick, Mednick, and Jung (1964), male undergraduates were selected from the top, middle, and bottom of a distribution of RAT scores and were requested to provide as many associations as possible to each of various words. A strong positive relationship was found between RAT scores and the number of associates generated. The high and medium RAT groups were comparable in mean intelligence levels, but the low RAT group had a lower intelligence mean. High, medium, and low RAT groups all were significantly differentiated from one another, however, in terms of associative productivity, thus suggesting that the contribution of intel-

¹⁰ The problem just described in connection with the Caron et al. study also applies to a study by Gall and Mendelsohn (1967), where association training once again involved repetition of a stimulus word each time a new associate to it was requested. In the Gall-Mendelsohn investigation, a facilitation effect was found for females but not for males.

ligence to such a relationship most likely was minimal¹¹

Riegel, Riegel, and Levine (1966) also have demonstrated the same kind of relationship. By using extreme-scoring undergraduates on a measure that has been found (Walker, 1962) to correlate highly with standing on the RAT, high scorers exceeded low scorers on number of responses offered in a free association task, number of different responses given to any particular stimulus in that task, and number of different responses offered to each stimulus in various controlled association tasks, that is, tasks where specific classes of associates were requested.

In general, it should be kept in mind that evidence reviewed earlier has suggested that individual differences in quantity and uniqueness of associative output seem to be relatively independent of intelligence, thus rendering it very implausible that intelligence accounts for the obtained relationships between these associative variables and RAT performance.

Given the demonstrated correlation between level of RAT performance and the generation of associative content, is there any evidence on whether the production of unusual associates to a stimulus by high RAT scorers is per se a goal or rather is simply a necessary by-product of generating larger numbers of associates to that stimulus? Research by Houston and Mednick (1963) suggests that it is a goal. Using undergraduates scoring at the high and low extremes of the RAT, these authors found in a word-preference situation that the high RAT group sought out words that entailed novel associates and/or avoided words that entailed common associates, while the reverse was the case for the low RAT group. The greater output of unique associates found in other work to characterize high RAT scorers therefore seems not just to constitute a by-product of their greater productivity but also to re-

fect a preference difference in favor of unique over common associates.

With RAT performance and the generation of plentiful and unique associates thus shown to be congruent operations, our further review of the RAT literature has evident bearing upon fluency and uniqueness of ideational associates as well. Since our consideration of earlier evidence has suggested that productivity and uniqueness of associates are relatively independent of functions concerned with intelligence and academic achievement, we should expect a sizable component of performance ability on the RAT to show the same kind of independence. Research on this issue will concern us next.

Relationships with Intelligence, Academic Achievement, Occupational Achievement, and Research Creativity The general picture seems to be one of varying relationships, averaging out to somewhere in the vicinity of zero, between RAT performance and assessors of intelligence and achievement—whether the achievement be measured in academic or occupational settings. The correlations with intelligence indices are positive, whereas those with achievement indicators tend to be negative. On the other hand, a strong positive relationship has been found between RAT performance and a criterion of research creativity as distinct from general intellectual ability and also as distinct from achievement even in research-oriented occupations. Let us turn first to the findings on achievement and traditionally assessed intelligence.

Regarding correlations with intelligence assessors, M. Mednick (1963) reported a correlation of .41 between RAT performance and Miller Analogies Test scores for a sample of psychology graduate students. For undergraduate subjects, Rainwater (1964) found the RAT to correlate .31 with a vocabulary test, Mendelsohn and Gussow (1966) obtained a correlation of .35 between the RAT and a different vocabulary test, and Laughlin (1967) reported a correlation of .48 between the RAT and Terman's Concept Mastery Test. Shared method variance—the fact that the RAT and the intelligence measures are administered as tests with a time limit—may account for some or all of this positive relationship. In addition, or alternatively, the finding supports the possibility that amount of stored information—for example, size of

¹¹ Level of RAT performance related not only to number of associates produced but also to rate of production, thus suggesting that the associative gradient for high RAT scorers not only has a flatter slope than that for low scorers, as the Mednick view implies, but also—contrary to the Mednick formulation on this point—may involve higher likelihoods for common as well as for uncommon associates.

vocabulary—may play a role in RAT performance

When we turn from intelligence assessors to academic achievement, the relationships with the RAT, if present at all, are found to be negative rather than positive. Thus a correlation of -0.27 was found between RAT scores and the first-2-year grade point averages for 74 undergraduates at an engineering school, while the same correlation of -0.27 was found between the RAT and summer grades for a smaller group of 34 summer school students at a liberal arts college (Mednick, 1962, Mednick and Mednick, 1964). The correlation was significant for the first sample, not significant for the second. M. Mednick (1963) reported a nonsignificant correlation of -0.11 between the RAT and grade point averages for a sample of psychology graduate students. The obtaining of additional negative correlations between college grades and RAT scores also has been mentioned (Mednick and Mednick, 1964).

The picture for occupational achievement seems to be similar to that for academic achievement. Studying scientist and engineer personnel in research settings, Andrews (1965) found either zero-order or negative correlations between RAT scores and various definitions of achievement on the job, such as number of publications over a 5-year period, or judgments by peers and supervisors of a man's overall usefulness to his organization. No explicit attempts to judge creativity were made. Rather, the performances assessed all were ones to which motivation for achievement against competition standards of success could make a sizable contribution. Tangible signs of success at competitive achievement, whether in academic or occupational settings, thus are unrelated or even inversely related to RAT scores. The trend toward negative correlations with the achievement indices suggests, indeed, that the kind of thinking reflected in high RAT scores may actually impair the pursuit of achievement success—a matter that will become more understandable later when we explore what seems responsible, apart from general intelligence, for the attainment of high RAT levels.

Two studies can be cited where explicit assessments of research creativity possessing high face validity were related to RAT scores

In the first (Mednick, 1962), 21 students of architecture were rated for creativity by faculty members who had been supervising the students for at least 1 and in many cases 2 or more years in the development of new designs for buildings. The correlation between creativity ratings and RAT scores was 0.70 , which was quite significant even with this small sample. No appropriate controls for intelligence, however, were reported. A second study (M. Mednick, 1963), on the other hand, obtained analogous results and included appropriate control information as well. Faculty research supervisors of 43 psychology graduate students who had been carrying out independent projects rated the students for research creativity. The definitional basis for the ratings—adapted from Taylor (1963)—concerned the student's ability to develop new research methods and/or to unite disparate areas of theory or of research in useful and original ways. The ratings for research creativity—made without knowledge, of course, of RAT scores—correlated very significantly (0.55) with the RAT but did not correlate with Miller Analogies Test scores (-0.08) or with grade point average (0.06). As already noted, RAT scores in this study correlated moderately with Miller Analogies Test scores but not with grade point average. The variance held in common by the RAT and the creativity ratings, however, clearly is different from the variance which the RAT shared with the Miller scores. We thus have begun to glimpse some evidence of what the RAT relates to apart from general intelligence. The component of the RAT that does not concern general intelligence is what correlates with the creativity ratings.

What is it that high scorers on the RAT may do that, on the one hand, leads to their earning high research creativity ratings but, on the other, actually may depress their average grade level? We have found that, whatever the process is, it has nothing to do with intelligence—although intelligence does make a contribution to RAT scores. A clue to the answer originates in another study concerned with academic grades, but this time from a different perspective. Walker (1962) administered the RAT to a sample of almost 600 high school juniors. Students scoring in the upper or lower 30% of the resulting score distribution were selected for further

study and equated for intelligence as indexed by the California Test of Mental Maturity Greater grade variance—variability from grade to grade earned by the student—was found for the high than for the low scoring boys (but not girls) on the RAT Perhaps—at least among the boys—the highs are willing to expend a great deal of effort on a course if it interests them—but they are equally willing to let their other courses slide Presumably therefore the attention of the highs is not automatically invested in academic subject matter but is more likely to wander to topics outside of the curriculum The highs may be more distractible on the basis of what the environment has to offer by way of varied stimulation, regardless of how relevant or irrelevant the stimulation may be to the pursuit of a narrowly and abstractly defined focus such as earning good grades to gain entrance to college The mechanism that begins to suggest itself on the basis of this line of interpretation—that highs are more inclined than lows to deploy attention from the center to the periphery of their field of action—has received direct investigation in the research to which we now turn

Attention Deployment as the Intelligence-Free Mechanism behind the Remote Associates Test. Can the directing of attention, as distinct from the providing of a solution-response, facilitate RAT performance? Our consideration of attention deployment should begin with this question, since an affirmative answer will encourage the attempt to understand individual differences in RAT scores in attentional terms Maltzman, Belloni, and Fishbein (1964) gave various prompting experiences to different experimental groups of undergraduates prior to solution attempts at each of a number of RAT problems The general character of all the prompting conditions involved presentation of a dominant associate of the solution-word before the subject tried to solve the given RAT problem What the conditions that maximized facilitation had in common, in contrast to the other conditions, was that the first conditions directed the subject's attention most specifically to the cognitive domain in which the search for the solution word should be conducted Such directing of attention was achieved in one case by a single presentation of the dominant associate of the solution word with

instructions to give the first associate that came to mind, and in another by 6 presentations of the dominant associate with instructions to write it down each time it was heard—but without any request to associate to it

Given the preceding demonstration of attentional processes in RAT performance, we can inquire whether it is a difference in how their attention is directed that underlies the characterization of high RAT scorers as possessing flatter associative gradients than lows Perhaps a flat gradient arises because attention is more readily deployed to lower likelihood associates a broader range of stimulus information was searched out regarding these associative possibilities in the first place, and/or a broader range of memory traces regarding this material is subjected to a search process Such a proposal could be given substance if we found high RAT scorers to display greater sensitivity to the utilizing of incidental cues from their external environment, for then we would have a correlate that is indisputably concerned with attentional scanning Whether such incidental cue utilization were based upon broader search patterns at the time of registration, in the course of storage, or at both times, we would know that breadth of attention deployment has a bearing upon RAT performance

Two studies that sought to relate breadth of attention deployment to individual differences in RAT performance obtained positive evidence but failed to include an intelligence control in their design, thus leaving interpretation of their findings ambiguous Mednick, Mednick, and Mednick (1964), in a variant of the Maltzman et al (1964) prompting study, found high RAT scorers to show greater facilitation from a presumably irrelevant prompting task than low RAT scorers High RAT scorers therefore were exhibiting greater incidental cue utilization than the lows

In the second study, which also lacked an intelligence control, degree of incidental cue utilization of high and low RAT scorers was investigated in a problem-solving context quite removed from the RAT Mendelsohn and Griswold (1964) explored the performance of 108 undergraduates of varying RAT levels in the following situation Each subject was given a list of 25 words to try to memorize in 10 minutes (the focal stimuli) while

another list of 25 words which the subject was told to ignore was played through 16 times on a tape recorder (the peripheral stimuli). The subject knew he would then have some presumably irrelevant problems to work on, following which there would be a recall test for the focal list. The problem task consisted of 30 anagrams—scrambled letters to be rearranged into a word. Ten of the anagram solutions were words from the focal list, ten were words from the peripheral list, and the remaining ten were from neither. After the period devoted to solving anagrams, the subject then was given 5 minutes to write down all the words he could recall from the list he had tried to memorize before—the focal list. The results were provocative. Mendelsohn and Griswold (1964) found that high RAT scorers exceeded lows in number of anagram solutions attained that were words from the focal list and also in number attained that were words from the peripheral list—both of which constituted, of course, incidental stimuli from the perspective of the anagrams task, with the peripheral stimuli in even more of an incidental role than the focal. The RAT groups did not differ, however, in their ability to recall the 15 words from the focal list that were not anagram solutions—the appropriate recall test since the groups differed in number of anagram solutions attained involving focal list words and thus in degree of experience with those words. Hence memory ability differences could not account for the results.

A more extensive investigation by Mendelsohn and Griswold (1966) with the same materials both replicated the above results and also found that although intelligence had a moderate positive relationship with the RAT, intelligence was unrelated to the utilization of either focal or peripheral incidental cues. That intelligence plays a role in RAT performance thus has nothing to do with the relationship between the RAT and incidental cue utilization. It is, rather, the intelligence-free part of the RAT's variance that accounts for its relationship with the measures of incidental cue utilization.

The interpretation just presented received further confirmation from a study by Laughlin (1967) with yet a different incidental cue utilization procedure, one which, as in the case of Mendelsohn and Griswold, involved a

problem-solving task unrelated to the RAT. Laughlin found that RAT scores were strongly related to degree of incidental cue utilization and were also, although less strongly, related to degree of intentional cue utilization. Intelligence scores, on the other hand, while once more related to the RAT, were not at all related to degree of incidental cue utilization or to degree of intentional cue utilization. Once again therefore it is the extent to which RAT performance is independent of intelligence that accounts for greater utilization of incidental cues on the part of higher RAT scorers. In striking corroboration of the Mendelsohn-Griswold (1966) study, Laughlin's work presents further evidence indicating that breadth of attention deployment underlies a sizable component of individual differences in RAT scores, and, indeed, the very component that has nothing to do with intelligence.

The Evidence in Retrospect The research inspired by the RAT has permitted us to come considerably closer to understanding the source of individual differences in productivity and uniqueness of ideational associates. The flatter associative gradients implied by high levels of these variables may well arise because of a penchant toward more diffuse or extensive deployment of attention in the reception of information, in its retrieval from storage, or in both.

Performance on the RAT has been found to depend in some degree on intelligence and in some degree on breadth of attention deployment. The empirically demonstrated relationship between individual differences in RAT scores and in ideational fluency and uniqueness on associative tasks cannot be mediated by intelligence, since associative fluency and uniqueness seem to be relatively independent of intelligence—a point that will receive further explicit documentation in the next section of the chapter. This leaves the intelligence-free variance of the RAT as the necessary source of its link with associative productivity and uniqueness, and it is specifically the intelligence-free variance of the RAT that has proven to be accountable for in attention deployment terms. This leads to the strong presumption that associative productivity and uniqueness are to be explained on the basis of an attention deployment mechanism.

Not only have we found breadth of attention deployment to constitute the process that accounts for the intelligence-free variance in RAT performance, but we also have found that it is only the intelligence-free variance on the RAT that in turn correlates with a criterion of research creativity. It thus seems likely that at least one important process eventuating in higher judged research creativity is a disposition to deploy one's attention from the center to the periphery of a task context—a greater readiness to utilize incidental cues.

As a final point to be made in this section, we are now in a position to clarify a theoretical issue that goes back to Guilford's initial formulation and which was previously unresolved. Recall that Guilford's concept of divergent thinking included heavy reference to flexibility—the postulation of various abilities to recenter or redirect thought processes as relevant to creativity in thinking. One can, indeed, find many references to one or another kind of flexibility in discursive treatments of what may be involved in creativity (e.g., Mandler and Kessen, 1959). Yet our review of the evidence on Guilford-type measures of flexibility indicated that the concept failed to be distinguishable from the general intelligence domain.

The role of an attention deployment mechanism in accounting for associative productivity and uniqueness, as suggested by our analysis of the RAT literature, permits us to see what kind of psychological meaning seems appropriate to attach to the flexibility notion in relation to creativity, and thus to resolve the apparent paradox just described. What Guilford meant by flexibility was a tendency to shift from one category of meaning to another, or, if you will, from one kind of logically defined entity to another. This kind of shifting concerns the application of rules of concept formation and logic, and hence must give emphasis to a process of judgment or evaluation of cognitive output in the light of such rules. The kind of flexibility to which the concept of attention deployment refers, on the other hand, is quite different. Broad attention deployment is defined as a tendency toward the wandering of attention away from a task focus along routes that have nothing to do with logic or classification but rather are strictly associative in character, whether the attentional wandering takes place in the course

of information registration, information retrieval, or both. Since the path traversed is an associative route, judgment or evaluation is at a minimum. While flexibility in Guilford's sense, then, seems indistinguishable from general intelligence, flexibility in the sense of broad attention deployment seems to have nothing to do with general intelligence and, indeed, seems rather to provide a basis for comprehending associative productivity and uniqueness.

The Research by Wallach and Kogan

Theoretical Considerations Wallach and Kogan (1965a, 1965b) began with the same conceptual approach to creativity as Mednick, following him in taking their warrant for this approach from introspective accounts by creative persons in the arts and sciences which emphasized the importance of associative flow and the freedom to entertain wide-ranging associative possibilities in a playful manner. Such points led Wallach and Kogan to formulate a definition of the creative process in terms of the following considerations: "first, the production of associative content that is abundant and that is unique, second, the presence in the associator of a playful, permissive task attitude" (1965a, p. 289). The second consideration aimed at describing a psychological state that would maximize the associative production in question, and the definition assumed that some criterion of relevance would have to be met by the associates produced.¹²

Although Wallach and Kogan's assessment procedures originated in Guilford's work, two differences prevailed. First, rather than embracing the range of abilities tapped in the Guilford research—with their varying degrees of independence from convergent thinking—the indicators used were limited to measuring productivity and uniqueness of ideational associates. Second, the procedures were administered in a manner that would maximize the opportunity to generate associates on the subject's part. In contrast to the time limits and testing context prevailing in the work carried out within the Guilford tradition, with their possibly inhibitory implications, the present

¹² Jackson and Messick (1965) also have called attention to cognitive playfulness as a means of predisposing the individual toward generating unusual associative combinations.

procedures were administered without time limits and in a setting structured to convey the impression that the materials were under investigation as potential games rather than constituting tests for evaluating the competence of the subjects

Both of the differences just described were dictated, of course, by the Mednick formulation: the first, in that associative processes should be the topic of concern, the second, in that maximal opportunity for the detection of the results of a shallow associative gradient should be present. Since, in turn, the Guilford tasks require that the responses offered by the subject must fulfill a criterion of relevance—for example, must be possible uses for a given object or possible similarities between a given pair of objects—the “relevance” or “usefulness” part of Mednick’s formulation also was met.

We turn next to a description of the five procedures used by Wallach and Kogan in their assessment of associative processes. Of these, three are concerned with verbally presented and two with visually presented stimulus materials.

Taking the verbal procedures first, the *instances* task requested the subject to generate possible instances of a class concept specified to him by the experimenter, such as round things or things that move on wheels. The *alternate uses* procedure requested the subject to think of as many uses as possible for a verbally specified object, such as a newspaper, a coin, a shoe, and a chair. The third verbal procedure was the *similarities* task, in which the subject was to generate possible similarities between a verbally specified pair of objects, such as a cat and a mouse, or milk and meat.

Moving on to the visual procedures, the *pattern meanings* task presented each of a number of abstract visual designs, with the subject requested to think of as many meanings or interpretations as possible concerning what each design might represent. In the *line meanings* procedure, finally, the same kind of request was made of the subject, with the stimulus materials this time consisting of various nonobjective line forms.

Two variables were derived from each of the five procedures: number and uniqueness of responses. Number of responses refers simply to the total output of ideas offered by a subject for a given item, and thus is a measure

of ideational fluency. Uniqueness of responses, in turn, refers to the number of fully unique ideas provided by a subject in the case of a given item—that is, the number of responses given by only one person in the sample under study to the item in question. Uniqueness thus is an index of the kind of originality or novelty that is defined in terms of statistical infrequency. In accordance with the Mednick formulation, it was assumed that uniqueness would tend to increase with a subject’s successive responses to an item, and hence that a subject who produces a larger number of responses also should generate a larger number that are unique.

Relationships with Intelligence and Academic Achievement. In addition to the 10 associative indicators just described—a productivity and a uniqueness measure—the 70 male and 81 female fifth graders in Wallach and Kogan’s work received 10 assessments concerning general intelligence and academic achievement. We turn now to a consideration of the individual-difference relationships among the 10 associative measures, among the 10 indicators of ability or achievement in the convergent thinking area, and between these two sets of variables.

The 10 associative variables, all of which proved to be highly reliable, were found to intercorrelate strongly for the sample as a whole and also for each sex considered separately. The average of the 45 correlations between all pairs of the 10 measures was .41, taking the sample of 151 children as a whole. Correlations were equally strong across verbal and figural procedures as within each of these domains, and the productivity and uniqueness variables correlated strongly both within a given procedure and across different procedures.¹³ The evidence was clear that the associative indicators in question defined a unitary dimension, with novel associates emerging as a function of greater response productivity and with consistent levels of performance obtained regardless of the nature of the five procedures used. Having demon-

¹³ In order to avoid artifactual inflation of correlations through part-whole contamination, the productivity measures that were used in these computations consisted of the total number of responses given by a child to an item minus those of his responses that were unique.

strated such dimensionality, however, the critical question is whether the degree of interrelationship among these 10 variables is appreciably greater than the degree of their relationship with the convergent-thinking domain.

The convergent-thinking assessors consisted of five measures that would be categorized as indicators of academic "aptitude" and five that would be considered indicators of academic "achievement." We have already found that the separation just described is difficult to maintain in practice, in that aptitude and achievement yardsticks turn out to be highly correlated. The 10 assessors covered verbal, quantitative, and performance definitions of intelligence and an array of academic subject matter skills. To what degree do the 10 measures intercorrelate? The results indicate strong intercorrelation for all of the convergent-thinking indicators in the case of the total sample and also for each sex taken separately. Considering the sample as a whole, the average of the 45 correlations between all pairs of these 10 measures was .51. No warrant was found in terms of correlational magnitudes for distinguishing between the ability and achievement indicators or among verbal, performance, and numerical skills.

Although the associative and the convergent-thinking measures thus were found to define strong and cohesive respective dimensions of individual differences, the relationships between the two kinds of assessors turned out to be uniformly low. With 10 measures in each of the two domains, there are 100 correlations between all pairs of the indices in the two groups. The average of these correlations was .09 for the total sample and was comparably low for each sex taken separately. That the measures in the two groups were essentially independent of each other and that each group in turn defined a strong dimension in its own right demonstrated that the associative variables had considerably more in common with one another than the degree of their relationship with intelligence.

The present evidence offers strong support for the Mednick formulation and also confirms the indications from earlier work that ideational fluency and fluency-dependent forms of uniqueness are maximally orthogonal to convergent-thinking skills. It may be that the virtually complete orthogonality demon-

strated in the Wallach-Kogan research depended in some degree on absence of time limitations and reduced evaluative pressure for the associative tasks, since the separation attained between such tasks and the convergent-thinking indicators seems more thoroughgoing than we found to be the case in at least some of the earlier work reviewed. On the other hand, we have noted in our analysis of other studies a substantial degree of separation from intelligence for Guilford-type measures of ideational fluency and fluency-based indicators of originality, even though such measures were administered as tests and with time limits. And the RAT, in turn, has been found to yield a strong, intelligence-free dimension of individual differences despite administration within a time limit—albeit a quite liberal one. Most likely, therefore, at least near-orthogonality between the associative variables and convergent thinking can be attained even when relatively constraining administration conditions prevail for the associative variables, with complete orthogonality perhaps requiring that the conditions of administration be more open.

In a recent study by Ward (1966) of pre-school age children who were heterogeneous with respect to socioeconomic background, three associative tasks adapted from the Wallach-Kogan work—two verbal and one visual—were administered together with the Peabody Picture Vocabulary Test as an index of intelligence. Scoring of the associative materials for productivity and uniqueness was carried out. The measures derived from the two verbal procedures cohered substantially and were independent of intelligence, whereas the results for the visual procedure were ambiguous. Ward (1968) also has reported that with a sample of 7- to 8-year-olds using similar procedures, the measures derived from all three associative tasks cohered significantly and were essentially independent of intelligence. Ward's work thus constitutes additional empirical support for the distinguishability from intelligence of the associative dimension that we have been describing.

Are there increases with age in the kinds of associative variable under discussion? It would, of course, be surprising if this were not the case to some degree, since the increase in amount of stored information that takes place with age must have at least some effect upon

associative output and number of unique associates. On the other hand, age-related increases have not been invariably obtained. Thus, for example, although Becher (1960) found college seniors to give a larger number of unique responses on a free association task than did college freshmen, Davidson and Longo (1960) found no increase in number of unique responses offered when free associating to various stimuli across an age range extending from fourth graders to college freshmen and sophomores. Davidson and Longo, indeed, were led to conclude from their evidence that "the diversity of associations is not a simple function of the number of different experiences or of developing verbal ability" (1960, p. 91). That any evidence at all can be found running counter to an age-related increase in such associative indices seems noteworthy, since it supports the view that size of storage reservoir is only one determinant of such variables and leads us back rather to the question of how the associates are organized—that is, the issue of gradient slope.

In sum, the evidence seems clear that there is a dimension of considerable generality concerned with associative productivity and uniqueness, and that this dimension stands quite apart from the traditionally demarcated domain of convergent thinking. Much of the work carried out by Wallach and Kogan was concerned with the search for correlates that would distinguish this associative dimension from that of general intelligence. We turn next to one of these correlates.

Evidence on Remoteness of Instances in Categorizing. Having found the associative variables and convergent thinking to define orthogonal dimensions, Wallach and Kogan (1965a, 1965b) proceeded to distribute their sample of children in terms of the subjects' standing on the two dimensions considered jointly. Potential correlates then were investigated concerning such areas as the social behavior and esthetic sensitivity of the children. Males and females were found not to differ in their average levels on the associative and convergent-thinking dimensions. Recall also that orthogonality between the two dimensions had been found to prevail in equal degree for both sexes. Nevertheless, the correlates were investigated separately for the two sexes, and many of the results indicated rather complicated sex differences in correlated

behaviors. As an example of the correlates that were studied, we shall consider a domain where the same findings emerged for both sexes. The question studied was how remote from one another are the instances which a child was willing to assign to a common class.

When the nature of a category is specified to a person, the boundaries of that category still will remain ambiguous in many cases. Individuals have been found to show systematic differences, in fact, regarding their preferred "category width" under such circumstances, that is, their inclination to broaden or narrow a specified category to include or exclude, respectively, instances whose membership status is ambiguous. Pettigrew (1958) constructed a series of questions in which the central tendency value of a category would be specified and the subject then requested to estimate, from multiple-choice alternatives, the most deviant instances of that category that might ever be encountered. One item, for example, concerned the typical speed of birds, another, the typical width of windows. In the first case, the boundaries to be specified were the speed of the fastest bird and of the slowest, in the second case, the width of the widest window and of the narrowest. Wallach and Caion (1959) adapted the Pettigrew instrument for use with children and found it to correlate with the child's willingness to assign visually ambiguous instances to an already defined category of geometric forms.

What psychological process is reflected in a person's disposition toward maintaining broad or narrow categories? To say that there is a differential willingness to entertain deviant instances as possibly relevant to a given class domain leaves the matter, after all, at a descriptive level. Necessary for attaining broad categories is some kind of mechanism whereby the focus of a person's concern moves outward from the most frequently encountered exemplars of a class to those that would be met only rarely. We therefore find ourselves looking for the same kind of mechanism that seems needed in order to account for productivity and uniqueness of associates, where again high performance means that the person must fail to stop at common associates to a task stimulus and instead must generate further ideas that bear a more deviant relationship to his starting point. From the evidence

considered earlier, we are led to speculate that the mechanism may be attentional in character, with the broad categorizer's attention more likely to wander toward doubtful instances of a class. At any rate, there seems good reason to expect some commonality in terms of process between a person's preferred category width and his levels of associative productivity and uniqueness. The ability to "see" possible relationships between instances of greater diversity—and hence to assign them to the same class—thus should be found in the case of persons more disposed toward a rich associative flow in response to a task request.

In the Wallach-Kogan research, the category width measure used by Wallach and Caron was administered. In addition to items on the speed of birds and the width of windows, other questions concerned such matters as the length of whales, the length of dogs, the speed of cars, and the width of roads. Wallach and Kogan found that in both sexes high associatives exhibited broader categorizing tendencies than low associatives. Intelligence level, on the other hand, was unrelated to category width, and there was no interaction effect between high versus low associative and intelligence levels in relation to category width. While the relationship between a child's standing on the associative dimension and his breadth of categorizing was stronger for females than for males, the obtained linkage was similar for both sexes, as also was the absence of relationship with intelligence or with the interaction between associative level and intelligence. It can therefore be concluded that category width is a correlate of associative level as distinct from intelligence. In somewhat the same way as Houston and Mednick (1963) found higher RAT scores to demonstrate a greater preference for novel associates, Wallach and Kogan found children who exhibit higher associative output and uniqueness to demonstrate a preference for entertaining unusual or deviant instances for membership in a category. The presence of flatter associative gradients thus seems to describe what is involved in setting broader category limits as well as in showing greater associative productivity and uniqueness. An acceptance of instances of greater remoteness as possibly warranting assignment to the same

category may describe the attitude that permits someone of high associative level to achieve the novel ideational combinations and integrations from which significant insights arise.

The Evidence in Retrospect. As the last three sections of the chapter indicate, restricting the definition of creativity to associative processes has yielded an evolving set of research strands, which all can be ordered in terms of the associative gradient concept. Each of the three traditions of studies that have been under consideration—work centering around Maltzman, Mednick's RAT, and Wallach and Kogan—served to further our understanding of how associative processes enter into thinking. The result has been a formulation which is quite distinguishable from the notion of convergent-thinking ability and which there is some reason to align with a term such as creativity. The formulation did not arise unheralded, of course, it was foreshadowed earlier in the chapter and was in fact found to emerge from what the evidence presented there seemed, upon interpretation, to suggest.

In the light of what we have learned concerning associative phenomena, we are in a position now to draw a tentative conclusion as to then major defining property as far as the creativity issue is concerned. The conclusion—one that has been hinted at in preceding pages—is that the crux of the matter revolves around the process of generating or producing associates without regard to evaluating them for relevance or applicability to a problem or task. Although novel associative content must be useful or relevant to qualify as creative according to such definitions as that presented by Mednick, the evidence we have reviewed suggests that sensitivity to relevance has but a tangential role in the thinking style which in fact leads to ideational content that is both novel and relevant. While a definition such as Mednick's or Maltzman's thus describes the nature of a creative thought product and sets down appropriate guidelines for fashioning operations that will capture such products, relevance sensitivity does not seem to be an important part of the process that eventuates in these products. What matters most is the generating of associates, once produced, the evaluation of their relevance

and appropriate action in the light of this judgment seems to pose little difficulty

The evidence for this conclusion arises from considering the range of associative procedures that have been found to be related to one another—both in terms of individual differences and in terms of experimental manipulation effects. This range runs the gamut from situations where judgments of relevance to a task are of paramount importance for a person's performance level to situations where evaluations of relevance play no part at all. Since the individual who shows up well in the former class of situations also shows up well in the latter, relevance sensitivity cannot play a strong role in a psychological account of what makes for his proficiency. What all the situations demand, on the other hand, is that the person generate associates in accordance with a flat rather than a steep gradient of response likelihoods. Let us recall some of the evidence in question.

In the course of the last three sections of this chapter, we have found, for instance, that training in the emitting of free associations to a stimulus—where virtually no relevance criterion exists for the responses—transfers to enhance a subject's performance on the unusual uses task, this is a situation where it is understood that one's responses must be relevant and not bizarre. So, also, we have found that free association training transfers to facilitate performance on the RAT, where the relevance criterion is so stringent that only one particular response will meet it. Individual differences in productivity of associates under completely free conditions, furthermore, have been found to correlate with RAT performance level. When we examine more closely the nature of what a person who is deficient at unusual uses or RAT performance can and cannot do, the issue of evaluating response relevance immediately is shown to be unimportant. Give a person who cannot suggest unique uses for a newspaper a list of the unique uses suggested by someone else, and that person has no trouble recognizing the relevance of the unique uses in question. Tell a person who cannot provide the solution to a RAT item what the answer is, and he easily sees that the answer-word is relevant to each of the three words constituting the problem.

Links do exist across performances ranging

from completely free association, where any response to a stimulus is acceptable, to procedures such as the unusual uses test, where responses must meet a minimum relevance criterion, to the RAT, where but a single response is defined as relevant. Generation or production of unique associates by virtue of a relatively flat associative gradient thus is seen to define the attribute of associative phenomena most relevant for creativity, and it is an attribute that possesses substantial independence from convergent-thinking skills. What we have come to is quite consistent, we might note, with the introspective accounts by eminent men in the arts and sciences cited earlier, where the emphasis seemed to be on ease of associative flow as such—evaluational processes being relegated to a later phase of work. Can we locate other correlates of associative output and uniqueness, however, that will permit us to obtain a clearer picture of their degree of behavioral generality? The final two sections of the chapter are addressed to this question.

FANTASY

As the term "fantasy" is used by psychologists, it typically refers to cognitive products having two characteristics: they rest to at least some degree upon associative relationships among their constituent elements, and they possess to at least some degree an integrated or sustained character. Given the utilization of associative material in fantasy, its character should be importantly influenced by the variables of associative productivity and uniqueness that we have been considering, and hence it should help define the implications of these variables. Given the potential significance of linguistic skills in the structure and expression of fantasy, however, it is evident that the role of verbal intelligence will have to be disentangled from a subject's fantasy behavior if we are to understand the part played in fantasy by associative processes. We have touched upon this issue before, here we turn to evidence that permits us to face it directly in the sense of determining as specifically as possible what aspects of fantasy rest upon the associative creativity dimension to which our review has led. First

we discuss some research on the TAT by Maddi and his associates

Research by Maddi and His Collaborators

Novelty of Story Productions on the TAT Scoring Considerations and Some Findings
We can view the Maddi group's research on fantasy as falling into two phases. In the first phase, three possible definitions of novelty or newness as reflected in TAT stories were explored, and some results were obtained which began to suggest that one of these definitions might tap the same vein as the associative creativity dimension. In the second phase, the definition that had looked most fruitful in this regard was in fact found to fulfill its promise. To begin, then, what were the three approaches to novelty in fantasy that were taken?

Curiosity, desire for novelty and novelty of productions were the labels applied by Maddi and his associates (see, e.g., Maddi, Charlens, Maddi, and Smith, 1962, Maddi and Berne, 1964, Maddi, 1965, Maddi, Propst, and Feldinger, 1965) to the aspects of TAT fantasy that they isolated for study. Scoring for *curiosity* was based upon content in which story characters ask questions, raise problems, or express perplexity, with the implication that new or further information would aid in resolving such puzzles. *Desire for novelty*, in turn, was defined as story content in which characters express interest in the novel and/or dissatisfaction with the familiar. Thus statements indicating concern with what is new, exciting, unusual, or different would earn scores for this category, as also would statements reflecting disenchantment with the status quo. Finally, *novelty of productions* referred to various categories of character treatment and plot that were judged to constitute unusual or infrequent ideational content on the part of members of the subculture in question. The categories of character treatment that earned scores were unusual role designations (e.g., uncommon occupations) and uncommon naming. The categories of plot treatment earning scores were unusual events (e.g., an illegal or catastrophic happening), novel interpretations (e.g., a story based upon paradox), and unexpected endings (an ending that violates an expectation generated by the preceding narrative).

A contrast can immediately be drawn be-

tween the last of these three scoring definitions and the other two. Whereas curiosity and desire for novelty both concern the expression of a subject's ideology or values regarding novelty-related behaviors, novelty of productions concerns the actual incidence of statistically infrequent story content—although inferred, to be sure, on the basis of judgmental approximation rather than actual counting. A further distinction should be kept in mind, however, between a person's verbalized values or ideology in relation to novelty and the actual preference behavior that he would exhibit when faced with more and less novel stimuli—the stimuli that he would actually seek to approach or avoid. Demonstrated preferences need not be in line with espoused doctrine. Curiosity and desire for novelty therefore do not concern preference for novelty but rather concern beliefs about how one should act toward various novelty-related issues. In novelty of story productions, then, we have a measure that looks as if it should reflect uniqueness and volume of associative output as defined in the kinds of task with which we are already familiar. In curiosity and desire for novelty, on the other hand, we have measures that stay close to the surface of expressed beliefs, telling us neither about actual incidence of novelty in the subject's story productions nor about actual preference for unusual ideational content.

The strongest finding in the first of the Maddi group's studies (Maddi et al., 1962) was that exposure to a period of monotony led to a decrease in novelty of TAT story productions relative to the results obtained under each of three other experimental conditions, all of which involved either a period spent in free activity or an attempt to provide novel stimulation to the subjects. These three conditions yielded similar outcomes. A contrast between greater and lesser monotony in the environment, then, was found to have a parallel effect on the level of novelty in obtained story content—less monotony eventuating in higher novelty production than greater monotony. If novelty of story productions can be primed by the environment, then the incidence of novelty in story content is behaving in a manner analogous to the incidence of novelty in detached associates as studied by the Maltzman group. When we turn to individual difference relationships, will story

novelty be linked with productivity of discrete associates and be relatively independent of intelligence?

In the first of their sets of data that bear upon this question, Maddi et al (1965) and Maddi (1965) provided some clues suggesting that the answer is affirmative, but the evidence remained ambiguous. Three tasks concerned with productivity regarding discrete associates were given to a sample of 62 male undergraduates. In one, the subject was to write down, during a 5 minute period, single words describing the feelings and sensations that he actually experienced, with number of words produced constituting the measure. In a second, the subject was to spend 5 minutes writing down any thoughts at all that came to him, with number of separate thoughts providing the measure. The final task requested the subject to list all the uses of a brick that he could think of during 5 minutes, with number of uses as the score. The three procedures just described were found to be strongly correlated among themselves but only marginally correlated with an index of verbal intelligence—thus confirming once again the presence of an associative creativity dimension. But what of relationships with novelty of story productions on the TAT? Whereas the novelty of productions measure was only marginally correlated with verbal intelligence, it was somewhat more strongly correlated with two of the three tasks that reflected productivity of discrete associates. To at least some degree, then, novelty of story productions was found to be linked with the associative creativity dimension in a manner that could not be explained away in full on an intelligence basis.

A further provocative lead was obtained from the material just described. Although positively correlated with the measures concerning output of discrete associates, novelty of productions was inversely correlated with what seems best described as a measure of random activity during a sham waiting period. The subjects found to be higher in novelty of story productions were those who waited more quietly—did not carry out as much manipulation of things in the office where they waited. One can interpret this finding as suggesting that the persons who produce a great deal of novel content in their stories are more likely to spend the waiting period im-

mersed in their own imaginings—and hence spend more time in general producing fantasies. As we shall note later, a similar kind of finding has been observed by Singer (1961) with children. Such a relationship again seems consistent with what would be expected if a linkage existed with the associative creativity dimension. Nevertheless, we would like to have firmer evidence of a bridge between associative creativity measures and novelty of story productions.

Novelty of Story Productions, Preference for Novelty, and Associative Uniqueness. The Evidence for a Syndrome. In a report by Maddi and Andrews (1966), 56 naval medical corpsmen trainees, ranging in age from 17 to 27 years and in education from ninth grade to several years of college, wrote stories in response to customary TAT pictures and instructions. Scoring of the stories was carried out for curiosity, desire for novelty, and novelty of productions. An adaptation of Guilford's uses task also was administered. Derived from this task was an index of the statistical infrequency of the uses offered. Correlations with originality of uses were .12 for curiosity, -.09 for desire for novelty, and .62 for novelty of productions. Not only was novelty of productions strongly related to the uses measure, but the other two story indicators were unrelated to the uses task. Correlations with general intelligence, on the other hand, were .27 for curiosity, .15 for desire for novelty, and .01 for novelty of productions. While highly correlated with uses originality, novelty of productions thus was quite independent of general intelligence. Such an outcome is particularly impressive in the case of the present sample, where the wide heterogeneity of educational level meant that chances for a relationship between intelligence and novelty of productions were maximized.

This demonstration was replicated on another sample by Pearson and Maddi (1966), which also explored a measure of preference for novelty. Included in the Pearson-Maddi research were the sample of naval medical corpsmen already described and a new sample of 40 undergraduate volunteers of both sexes. For the second sample, novelty of story productions correlated .42 with originality on the uses task but only .05 with a verbal intelligence indicator, thus repeating the findings

described for the corpsmen. A novelty preference measure—the Similes Preference Inventory—was devised and administered to both samples. Each of the items on this instrument presented the beginning of a common simile followed by five alternative endings from which the subject was to select the one he most preferred. Of the five possible endings for each simile, two were designed to be more usual and the other three more unusual. Scoring depended upon the number of similes for which an unusual rather than a usual ending was selected. Note that the present indicator represents a measure not of beliefs or values concerning novelty, but rather of actual preference behavior where a choice must be made which will favor stimuli of greater or lesser novelty. Novelty preference was found in this study to be related both to novelty of story productions and to associative uniqueness, while at the same time also standing independent of intelligence. It was furthermore found that novelty preference did not relate significantly with either of the other two story measures. Not only, then, has the relationship between novelty of productions and associative uniqueness been replicated in the Pearson-Maddi study, but two independent demonstrations of the relationship between each of those variables and preference for novelty have been provided as well. Intelligence—already known to be essentially independent of associative uniqueness—has been shown in two replications to be likewise independent of novelty of story productions and of preference for novelty. Finally, neither of the remaining story indices—curiosity or desire for novelty—showed relationships with associative uniqueness or with novelty preference.

It will be recalled that previous evidence already testified to a connection between associative uniqueness and novelty preference. RAT performance and novelty preference were found to be related. The present findings linking associative uniqueness with novelty preference offer further evidence for this relationship.¹⁴ We are therefore left with

¹⁴ A study also can be cited in which description of oneself as preferring novelty—although a belief-centered type of index—was found to correlate significantly with ideational fluency and originality scores on the uses task for sixth-grade children (Penney and McCann, 1964). In the

strong evidence in support of the view that the generating of unique associates reflects a preference for unusual ideational content as well as coming about as a necessary consequence of high associative output. Turning to the data on TAT stories, it has become clear that the associative creativity dimension has strong implications for one particular aspect of fantasy—the novelty or unusualness of its actual content. Expression in fantasy of beliefs supportive of curiosity or of the search for novelty is the result, however, of determinants other than the disposition to produce plentiful and unique associates. That associative creativity generalizes to the novelty of a person's TAT productions is of no small importance, of course, since this finding serves to broaden the behavioral arena for which associative productivity and uniqueness have demonstrable consequences. With clear relationships thus shown to obtain among novelty of TAT fantasy productions, preference for novelty, and associative uniqueness, we shall consider next some strands of further research in which assessment of fantasy has played a major part.

Singer's Studies and Related Work

Terms such as "imaginative play" and "day-dreaming" refer to forms of fantasy that are spontaneous, in contrast to, for example, TAT stories or Rorschach responses, which represent forms of fantasy that are elicited by an experimenter's request. As types of spontaneous fantasy, the difference between imagina-

Penney-McCann investigation as well as in a subsequent study by Penney (1965) that was also conducted with children, the self-descriptive measure of novelty preference—the Children's Reactive Curiosity Scale—proved to be independent of intelligence. Of possible relevance in addition is research by Teeter, Rouzer, and Rosen (1964), where third-, sixth-, and ninth-grade children were asked if they would rather look at a list of information that many people know or that only a few people know. Expressions of preference for the novel list—with the expectation that one would then receive the preferred list—were found to be independent of intelligence for both sexes at all grade levels. No relationships with associative measures, however, were investigated. Similarly, expressions of novelty preference and incidence of unusual interpretations of visual figures were found by Acker and McReynolds (1967) to be related in a college student sample.

tive play and daydreaming would seem to reside in the question of task relevance. If the self-generated fantasy behavior is relevant to some immediate task faced by the person, we tend to consider it imaginative play, if it is irrelevant to the immediate task he faces, on the other hand, we tend to consider it daydreaming.¹⁵

In the preceding part of the chapter, we discussed some evidence on a type of elicited fantasy—TAT stories. Now we turn to work which concerns spontaneous as well as elicited fantasy.

Incidence of Spontaneous Fantasy, Novelty of Elicited Fantasy, and Associative Creativity: Evidence on Relationships. The link between novelty of elicited fantasy and associative creativity already has been documented—at least for TAT stories—in the work by Maddi and Andrews (1966) and by Pearson and Maddi (1966). But what of spontaneous fantasy? Let us turn first to work relating spontaneous fantasy to novelty of elicited fantasy. A study by Singer and Schonbar (1961) with female graduate students assessed spontaneous fantasy by asking the subjects to indicate the frequency with which they experienced each of a large number of daydreams. This type of daydreaming questionnaire—reported on in more detail by Singer and McCraven (1961) and Singer (1966b)—presents a heterogeneous range of daydream content and has been shown to possess high internal consistency. Singer (1966b) furthermore has noted that high scorers in general subscribe to daydreams that are more fantastic or unlikely of occurrence. Regarding novelty of elicited fantasy, the subjects were asked to write an original story and also to write an account of an actual daydream. These two written products were scored in terms of five criteria—degree of novelty of materials, novelty of character, novelty of time sequences, novelty of spatial sequences, and emotional vividness. A total score was derived. Four of the five scoring considerations—all but emotional vividness—concern the introduction of one or another kind of novel content, and thus seem quite analogous to Maddi's scoring system for novelty of productions "Creativity in storytelling" as defined by Singer.

¹⁵ On daydreaming as task-irrelevant spontaneous fantasy, see, e.g., Singer (1966a), Antrobus, Singer, and Greenberg (1966).

and his associates thus appears to represent the same variable as the Maddi group's "novelty of productions" concept, and hence we shall continue to use the latter term. The Singer-Schonbar research yielded a correlation of .48 between novelty of written productions and frequency of daydreaming. Furthermore, independence from verbal intelligence was found in the case of both variables. A clear demonstration has been provided, then, of the linkage between incidence of spontaneous fantasy and novelty of elicited fantasy, and of the independence of both from the intelligence domain.

The same kind of demonstration was presented in a study of children of ages 6 to 9 by Singer (1961). Degree of spontaneous fantasy was defined in terms of the answers to four interview questions, two of which concerned play and the other two daydreaming. The play questions inquired about the child's favorite game and about the games he plays when playing alone. Choice of games requiring imaginative play in contrast to vigorous physical activity earned positive scores. The daydreaming questions asked whether the child ever has pictures in his head and whether he has a make-believe playmate. The spontaneous fantasy measure was found to be independent of intelligence, age, and sex, but was strongly related to novelty of storytelling productions. The interview measure also was found to be related to each of two overt behavioral indicators of the tendency to engage in spontaneous fantasy, thus offering validation for the self-report questions. The overt behavior indices concerned "waiting ability" and were introduced in the context of selecting people for enduring the solitary confinement of space flight. The children able to wait the longest were those who filled the interval with imaginative play—making believe, for example, that they were piloting a rocket ship. A study by Singer and Chipman (1961) provided the same kind of overt behavioral validation for a children's version of the daydreaming questionnaire. Whether spontaneous fantasy is measured in terms of a daydreaming questionnaire as in the Singer-Schonbar study or in terms of the kind of interview questions asked in the Singer (1961) research, such intelligence-free relationships have been obtained with novelty of elicited fantasy productions.

Other evidence supporting a relationship between spontaneous fantasy and novelty of elicited fantasy can be cited as well, and we shall give a few more brief examples. Page (1957), for instance, found that incidence of daydreaming was linked for female undergraduates with the giving of M responses on the Rorschach. With M responses relatively unusual as such, they were rendered even more novel in the Page study by crediting for M only if movement was clearly verbalized in a person's first response to a blot and only if the response was not a popular one. In an investigation by Riess (1957), children exhibiting greater restraint during a waiting period—and hence presumably more make-believe play—were found to offer a greater frequency of M responses on the Rorschach.¹⁶ Preference for toys requiring minimal motor activity and maximal spontaneous fantasy participation—such as a science kit or a fort with toy soldiers in contrast to a basketball or a baseball bat—turned out in a study by Lesser (1962) to characterize children who showed more unusual imaginal content in

¹⁶ We should hasten to emphasize that, notwithstanding relationships such as have just been described, the meaning of M scoring on the Rorschach is far from clear. There have, for example, been considerable variations in scoring criteria and stimulus materials. Thus the fact that Griffin (1958) failed to obtain a relationship between M scores and subjective creativity ratings of undergraduates equated on intelligence may have been due to the use of a set of ink-blots—the Legy Movement Blots—specifically designed to elicit M responses. As a consequence, M responses may have been rendered too likely in that study. On the other hand, further results favoring a linkage between one or another definition of plentiful spontaneous fantasy and one or another type of M scoring are contained in Barron (1955), Myden (1959), and Clark, Veldman, and Thorpe (1965). Further, a study by Doris, Sarason, and Berkowitz (1963) linking self-reported anxiety with M responding for second graders may be of relevance on the assumption that the former measure reflects introspective sensitivity. In a recent study, however, Swartz (1965) found just the reverse relationship, with higher M scores earned by the low-anxious children. With this type of elusiveness characterizing the M concept, it is doubtful that the kinds of theoretical promissory notes offered in favor of M by such writers as Stark (1964, 1965a, 1965b, 1966) will soon be cashed in

their TAT productions and Rorschach responses. Since incidence of reported night dreams constitutes a form of spontaneous fantasy that is known to correlate with frequency of daydreaming behavior (see, e.g., Singer and Schonbar, 1961), we also might note a study by Adelson (1960), where undergraduate females reporting night dreams that contained more unusual content also were found to show greater originality in choice of theme and treatment in creative writing products.

With evidence in hand supporting relationships between spontaneous fantasy and novelty of elicited fantasy as well as between the latter and associative creativity, can the circle be completed with findings showing that spontaneous fantasy and associative creativity are linked? Regrettably, the explicit evidence on this question is relatively meager, although—in the light of the material already reviewed—it would be most surprising if this link were not present. Positive support for the link was provided by Page (1957), who found that frequency of daydreaming among college females was strongly related to the number of ideational responses offered per Rorschach card. The number of different constructions by the subject as to what an ink-blot suggests is, of course, an index of associative productivity. Interestingly enough, whereas the number of different responses given to a blot stimulus was highly related with incidence of daydreaming, the sheer number of words given per response or per stimulus card was unrelated to the daydreaming index. This is precisely what we would expect on the assumption that number of words reflects verbal intelligence, since it has been demonstrated that daydreaming frequency as well as associative productivity are independent of intelligence.

Apart from Page's results, however, the only other relevant study yielded an ambiguous outcome. Singer and Antrobus (1963) found, with male freshman subjects, only a trend toward relationships between daydreaming frequency and certain Guilford tasks. However, the array of Guilford procedures—chosen to cover the whole range of factors distinguished by him—all were administered with brief time limits. We have already noted how time pressure can mitigate against attaining high levels of associative

creativity The brief time limits utilized in the Singer-Antibus research thus may have heavily restricted the range of individual differences concerning productivity and uniqueness of associates on those of Guilford's tasks that tapped these characteristics In the Page study, no such time pressure was operating

It seems fair to conclude that the connection between novelty of elicited fantasy and associative creativity can be extended at least tentatively to include incidence of spontaneous fantasy as well In closing this section, there is a further point that we should like to mention It is that spontaneous fantasy—especially of the daydreaming variety, where the cognitive activity is task-irrelevant—can be readily interpreted in terms of breadth of attention deployment Daydreaming represents a form of attentional wandering par excellence Inclusion of spontaneous fantasy in the correlational network surrounding associative creativity thus provides further support for an attention-deployment interpretation of associative creativity

The Question of Origins Since some work has been carried out on the issue of factors influencing the development of fantasy, clues may be at hand for understanding how associative creativity develops also Most of what can be said, however, remains quite speculative To begin, there is evidence suggesting that visual experience is particularly likely to form the raw material for fantasy Thus, for example, Singer and McCraven (1961) found that most of the daydream reports they gathered involved visual imagery Maupin (1965), in turn, reported that level of involvement in carrying out quiet contemplation or meditation was correlated with the amount of visual imagery obtained in a free association task The result did not appear to be accountable for in terms of a simple relationship with intelligence Moreover, Singer and Streimer (1966) compared blind and sighted children who were matched for intelligence, sex, and socioeconomic background, with the result that the sighted group substantially exceeded the blind group regarding incidence of spontaneous fantasy and novelty of elicited fantasy productions It is possible, then, that the availability of varied visual experience is particularly conducive to fantasy development At the least, it seems

that, contrary to psychoanalytic formulations, fantasy is more likely to reflect a perceptually rich environment than to arise in compensation for the blocked expression of impulses This is an etiological proposal that has been made by Singer (1966b), who goes on more specifically to suggest that fantasy may constitute the internalization of play

Drawing on Piaget (1962), White (1959, 1963), and Schachtel (1959), Singer suggests that the child engages in spontaneous play activity when pressing urges are relatively quiescent, utilizing, for this play, raw materials provided by the environment For the very young infant, phenomena associated with one's own body will suffice—for example, the appearance and disappearance of the baby's hands in his visual field Subsequently, raw material of a more complex order is needed—thus making important the provision by parents of varied experience, as well as the leisure and privacy to carry on playful commerce with a heterogeneous range of environmental stimulation Pressures toward cognitive economy then force the progressive internalization of play into thought, since the child becomes increasingly unable to find the time for re-creating games in all their full-blown response characteristics and instead must store their associative content in a form—fantasy—that can be used privately While such a proposal is influenced by Piaget, its aim is not to characterize the role of play in moving the child toward more sophisticated expressions of general intelligence—which is, as Sutton-Smith (1966) has observed, Piaget's basic orientation—but rather to claim for play a crucial role in fantasy—a type of cognitive activity whose spontaneous incidence and novelty cannot be predicted from level of general intelligence What kinds of evidence bear upon this proposal?

Singer (1961) found that children showing higher levels of spontaneous fantasy activity differed from those showing lower levels by reporting more interaction with their parents that would involve fantasy, such as games and storytelling, a higher degree of personal, extensive contact in general with a parent, and less involvement with siblings by virtue of being the oldest child, an only child, or having fewer older siblings These results constitute particularly good evidence since the high and low fantasy groups did not differ

regarding intelligence. On the other hand, there is the problem that the kinds of familial situations described here in contrasting high and low fantasy children also are ones that would tend to differentiate higher from lower intelligence children. Abstract thought capacities and the ability to work with language and other formal systems should likewise be enhanced by the family circumstances that have been described as fostering fantasy. Thus consider the following results obtained by Helson (1965, 1966). With a sample of 135 female college seniors, a checklist of childhood activities was administered and a measure was developed concerning the extent to which the subject had derived pleasure from a subset of activities concerned with imaginative play and artistic expression. This measure, however, was found (Helson, 1966) to correlate beyond the .01 level both with verbal Scholastic Aptitude Test scores and also with grade point averages.¹⁷ Helson (1966) points out that the measure of childhood concern with imaginative play and artistic activities that she used in her earlier study (Helson, 1965) was based on fewer items and had weaker relationships to presumed creativity criteria than the measure used in her later study. Ironically, however, the newer measure also has stronger relationships to verbal aptitude than the older measure. An early childhood setting that should promote fantasy involvement, therefore, as reflected in recollections of such activities as solitary play, writing of poems and stories, and creating of complicated imaginary situations, is found to eventuate in higher levels of verbal intelligence and academic achievement.

While a close parental relationship, the carrying on of games and storytelling with parents, and the time and privacy for solitary play activities all can be expected to foster the development of fantasy capacities, they hence can be expected to enhance general intellectual functioning as well. Although sub-

¹⁷ Among high scorers on the activities cluster just described, those nominated as creative by their teachers also were found to have significantly higher verbal SAT scores and grade point averages than those who were not so nominated. The teachers' creativity judgments thus were reflecting traditional intellectual criteria, just as were the scores on the childhood activities cluster in question.

tle differences may well exist between intelligence- and fantasy-promoting family background characteristics in terms of greater parental tolerance for deviation from reality and hence for error on the child's part as more conducive to development of fantasy, such differences may be difficult to tease out empirically. One comes away with the feeling that a major source of variance concerning individual differences in the novelty of elicited fantasy and the incidence of spontaneous fantasy—and hence, presumably, also in associative creativity—resides in hereditary factors. For example, Scarr (1966) found identical twins to be more similar to each other than fraternal twins in the amount of time spent viewing novel stimuli. Given the environmentalistic bias of our culture, it seems likely that the role of heredity in the present domain is much greater than has been assumed, thus rendering it eminently worthy of investigation.

Finally, we should note that—whether based upon environmental or hereditary considerations or both—there is evidence indicating that the kinds of fantasy and associative indicators that we have been considering are related to self-report scores on manifest anxiety indicators. Such evidence suggests that manifest anxiety indicators may function more as indices of introspective sensitivity than of pathology—at least in grossly normal samples. To begin with, consider that relationships between manifest anxiety scores and intelligence measures are found to be zero or negative, but never positive (see, e.g., Spielberger, 1958; Sarason, Davidson, Lighthall, Waite, and Ruebush, 1960; Ruebush, 1963). This implies that linkages between higher anxiety scores, on the one hand, and higher scores on the fantasy or associative indicators, on the other, cannot be mediated by higher intelligence levels. And linkages of this kind have been obtained in several studies.

Maddi and Andrews (1966) found manifest anxiety scores to be positively correlated with novelty of TAT story productions. So also, both Singer and Schonbar (1961) and Singer and Rowe (1962) found positive relationships between manifest anxiety indicators and frequency of daydreaming. Analogous positive correlations have been obtained between manifest anxiety and another arena of spontaneous fantasy activity—incidence of

night-dreaming, as inferred from dream reports (Schonbar, 1959, Singer and Schonbar, 1961, Tart, 1962) or from amount of sleeping time during which periods of rapid eyeball movement occurred (Rechtschaffen and Verdone, 1964) Turning to associative behavior, Davids and Enksen (1955) reported a positive relationship between manifest anxiety and an index of associative productivity—the number of associates offered in response to each of a variety of stimulus words Both the anxiety and the associative productivity measures, in turn, were independent of general intelligence and academic achievement for the undergraduates in the study Wallach and Kogan (1965a, 1965b) found—in the case of boys but not girls—that high associative productivity and uniqueness were linked with intermediate rather than low levels of manifest anxiety And in a possibly relevant study concerned with preferences for “feminine” versus “masculine” play activities, where the feminine emphasized imaginative fantasy and dramatization, whereas the masculine em-

phasized forceful physical contact and large-scale motoric involvement, Sutton-Smith and Rosenberg (1960) found that preference for the games involving imaginative play rather than extensive bodily movement was greater among the high-anxiety than the low-anxiety boys All in all, the results just reviewed seem to argue for greater introspective sensitivity on the part of persons displaying the types of fantasy and associative behaviors with which we have been concerned However such sensitivity arises, it may well be causally implicated in associative creativity, novelty of elicited fantasy, and incidence of spontaneous fantasy

In this chapter the question of locating and conceptualizing psychological processes to which the term “creativity” can be justifiably applied has been our main concern Given the encouraging results of this enterprise, next on the agenda for the psychology of creativity should be the study of how these processes are implicated in the attainment of products judged creative by the society

18. *Individual Variation in Cognitive Processes*¹

JEROME KAGAN and NATHAN KOGAN

with the assistance of Anne L. Bloxom and Regina Yando

The traditional insularity among the complementary processes of thought, motivation, and behavior is being overcome, making it necessary to invent concepts that reflect the new relations among these processes. The introduction of the concepts of field independence, reflection-impulsivity, leveling-sharpening, automatization, and creativity reflects an initial attempt to provide structure to the reliable variability that is characteristic of cognitive functioning among humans. The theoretical substance of these concepts typically implies that a blend of biological and motivational variables is responsible for the public phenomena. The vigorous and systematic study of variability in cognitive products represents a return to an interesting topic rather than a new frontier. Sir Francis Galton and James McKeen Cattell directed much investigative energy to individual differences in quality of cognitive functioning. Cattell, as early as 1890, proposed 10 tests that could be used to evaluate differences among people. The procedures included dynamometer pressure, rate of movement, two-point skin threshold, pressure causing pain, least noticeable difference in weight, reaction time to sound, time for naming colors, bisection of a 50 centimeter line, judgment of 10 seconds time, number of letters remembered on one hearing (Cattell, 1890).

Four of these tests focus on temporal functions and the rest assess sensory acuity or simple motor skills. This early battery mirrors the intellectual prejudices of the nineteenth century. Speed of nerve impulse conduction and psychophysical functions were dominant

empirical and theoretical issues, and it was reasonable to conclude that differences in quality of thought were the sequelae of differences in sensitivity of receptor function and central nervous system transmission speeds.

The contrast with today's tests is instructive and encouraging. A modern-day Cattell might select a test battery that included verbal analogies, object sorting tests, memory for digits and sentences, the rod and frame test, embedded figures test, verbal fluency, haptic-visual matching test, Stroop color word test, and matching familiar figures.

The contemporary battery evaluates richness of language, reasoning, classification, and perceptual synthesis and decision processes. The contemporary tests are clearly more cognitive and complex than those devised 80 years earlier. Immediate memory represents the only node of overlap, and its survival attests to its centrality in cognition.

¹ Preparation of this chapter was supported in part by Research Grant MH-8792 from the National Institute of Mental Health, Contract No. 43-65-1009 and Research Grant 1 PO1 HD-01762 from the National Institute of Child Health and Human Development, and a grant from the Carnegie Corporation of New York. Various people contributed to the preparation of this chapter. We are indebted to Laura Carde, Ann King, Katherine Moore, Doris Simpson, and Terry Stagman for their invaluable assistance. This chapter has profited from the comments and criticisms of Walter Emmerich, Roy Shore, William Ward, and Sheldon White, but the authors assume full responsibility for its contents.

The Current Concern with Cognition

A concern with social-class differences in school performance, creativity, and new discoveries in personality research has sparked the contemporary analysis of systematic variability in cognition. The awesome differences between lower- and middle-class children are apparent to even the most inexperienced observer. The lower-class child has a sparser language reservoir and is more impulsive than his middle-class peer. These cognitive characteristics contribute to the lower-class child's poorer performance in school. It is imperative that we inquire into the origins of this deficit and the mechanisms of its development.

The second incentive was born from the concern with creativity and the need to differentiate, among the verbally proficient, those who had fluent, flexible, and novel approaches to problems from those whose hypotheses were normative and stereotyped.

A third force stems from the insights of personality theorists who demonstrated not only that motives and conflicts affected perceptual and problem-solving performance, but also that responses to traditional personality tests—be they projective or objective—were as strongly influenced by cognitive as by motivational forces.

These three diverse historical forces have led to a substantial body of literature, but, equally important, they have provided a fresh perspective to our view of cognition.

The Emphasis on Cognitive Processes Psychology has returned for the second time to court the problems of mental life. The turnabout of the last decade is appreciated if one compares the last issue of *Child Development* in 1967 with the last issue 10 years earlier. Whereas 20 of the 27 empirical papers in the December 1967 journal were inquiries into cognitive functioning, there were none in the December 1957 issue. The return to internal processes reflects more than a cyclical change in popularity of a topical area. The return is characterized by a realization that psychology is not only the "science of the study of behavior," but also the science of the structure of mental life. We are beginning to acknowledge the potential validity of three important premises.

First, a particular motive, conflict, or expectancy will lead to different behaviors at

different ages or in different contexts. The child with a strong motive for social recognition may work hard in the school setting or be mischievous in a recreational setting. He may choose academic success as a route to recognition if he grows up in a middle-class neighborhood, he is likely to choose antisocial aggression if he is reared in a lower-class, urban setting. He may tease his mother at age 3 and compete with his peers at age 15. This principle is analogous to the concept of pleiotropy in genetics, where a particular gene can have different manifest effects (King, 1967).

Second, it is likely that the possible variety in behavior cannot match the potential variety of covert cognitive processes. As a result, a particular behavior must be in the service of many different processes. Consider the relatively simple response of smiling. The smile can reflect an insight, a reaction to a joke, a familiar greeting to a friend, or a hostile feeling. Similarly, the cry can mirror sadness or joy, dependence or fear.

Finally, each response is typically multi-determined—the result of more than one fundamental process. This principle is analogous to the concept of polygeny in genetics, where many genes act in concert to produce a particular manifest character (King, 1967).

These three premises require that psychology be as much concerned with cognitive processes as with behavior. An analogy to our sister sciences may be helpful. Chemistry is defined as the science of the structure of matter, not the science that studies public manifestations of these structures. Contemporary biology is more concerned with the structure of genes and proteins than with the morphological characters that are the final result of the actions of these units. However, 400 years ago each of these natural sciences took the study and explanation of external features as its central mission. All natural sciences begin their inquiries with the public phenomena that they wish to explain. With maturity, however, they turn their attention to the more covert hypothetical processes that must form the basis of their theories. Psychology may be beginning to make the critical turn from preoccupation with interesting external phenomena to the internal processes upon which the public behaviors rest.

One danger to be avoided in this regard is to assume necessarily an isomorphism be-

tween the terms in which behavior is conceived and the terms used to describe relevant internal processes. Treisman (1968) has noted

A Martian arrives on earth and for the first time in his life sees an automobile, something completely new to him. He is puzzled by it. He watches how it performs and finds that automobiles hold the road well or poorly, have high or low maximum speeds, travel downhill better than uphill, prefer smooth roads, and never fly or swim. But when he opens the hood and looks inside, all he sees is bits of metal, various wires, and a tank of smelly fluid. There is nothing that looks like the maximum speed, or the road-holding ability. He concludes that the automobile's behavior cannot be explained in terms of what lies under the hood, and he gives up in despair. Our position is similar when we want to explain the behavior of a human being, in health or disease. We have to try to discover what its structure is and the laws which govern its functioning. Not until we have got these straight can we see how far they explain human behavior (pp. 460-461).

The task is to gain full understanding of the structure of behavior, the structure of cognitive processing, and the mechanisms that join these two domains. It is possible, and indeed likely, that the structure of behavior does not match that of cognition. The heuristic assumption of the 'fifties that internal thought processes be treated as if they were overt responses may have outlived its usefulness.

A Definition of Cognition

The term "cognition" has typically referred to mental activities in the sense of both product and process. In this chapter, cognition stands for those hypothetical psychological processes invoked to explain overt verbal and motor behavior as well as certain physiological reactions. Cognitive process is a superordinate term, subsuming the more familiar titles of imagery, perception, free association, thought, mediation, proliferation of hypotheses, reasoning, reflection, and problem solving. All verbal behavior must be a product of cognitive processes, as are dreams and intelligence

test performances. But skeletal muscle movements or visceral reactions are not necessarily linked to cognition.

At a metatheoretical level, it is possible that the units comprising the essence of cognitive processes may eventually be recognized as the structures currently missing in psychological theory. Contemporary psychology seems to be a science of functions searching for its basic units. The laws of biology, chemistry, and physics consist, in the starkest sense, of collections of functional statements about entities. In biology the cell and the gene are the basic units, and the principles of biochemistry describe their functions. In chemistry the molecule and atom are fundamental units, and the principles of chemistry describe how these units behave. In physics particles and planets, are units, and the laws of particle decay and planetary motion describe the functions of these units. Psychology's units may turn out to be cognitive structures, and laws about cognitive process will describe how these units function.

The Mission of This Chapter

This chapter contains three related sections. The initial theoretical discussion analyzes the historical basis for the interest in individual variation in cognitive functioning. The long section that follows considers some salient sources of individual differences in cognition. It focuses on the dimensions that have come to be called, perhaps unfortunately, cognitive style and presents a detailed review of the concept of field independence. And the final section examines the role of motivational forces on the quality of cognitive functioning.

Lest the reader fear that we have taken too large a responsibility, we list here what is omitted. We shall not dwell on differences that are associated primarily with age, a topic central to several other chapters. Indeed, a developmental description of cognitive functioning is one of the central concerns of this book. Similarly, we shall not be concerned, in any bibliographic detail, with the differences that are associated with social class, mental retardation, or psychopathology. These issues are considered adequately elsewhere in this book. The major goal of the present chapter is to review and summarize some of the contemporary constructs invoked to explain individual differences in cognitive

The Mission of This Chapter

This chapter contains three related sections. The initial theoretical discussion analyzes the historical basis for the interest in individual variation in cognitive functioning. The long section that follows considers some salient sources of individual differences in cognition. It focuses on the dimensions that have come to be called, perhaps unfortunately, cognitive style and presents a detailed review of the concept of field independence. And the final section examines the role of motivational forces on the quality of cognitive functioning.

Lest the reader fear that we have taken too large a responsibility, we list here what is omitted. We shall not dwell on differences that are associated primarily with age, a topic central to several other chapters. Indeed, a developmental description of cognitive functioning is one of the central concerns of this book. Similarly, we shall not be concerned, in any bibliographic detail, with the differences that are associated with social class, mental retardation, or psychopathology. These issues are considered adequately elsewhere in this book. The major goal of the present chapter is to review and summarize some of the contemporary constructs invoked to explain individual differences in cognitive

functioning. We trust that a reasonable integration of this material is feasible.

THEORETICAL BACKGROUND

A thorough account of the theoretical-historical background of current research on the cognitive structures of children would be no less than a history of cognitive psychology. Clearly, such a venture is well beyond the scope of this one chapter. We shall not attempt to describe the various theoretical forces that contributed to make the study of cognitive processes the large-scale enterprise that it is today. Excellent historical treatments are available elsewhere (e.g., Dember, 1964; Mandler and Mandler, 1964). Rather, we shall confine our attention to more recent theoretical efforts that bear a relation to current research on the differential cognitive structures of children. The theorists most relevant to "individuality and cognitive performance" in children are the psychoanalytic ego psychologists, and those theorists who have been concerned with problems of psychological differentiation and integration—Lewin and Werner, in particular. Since separate chapters of this book are devoted to each of the foregoing theories, the theoretical discussion offered here will be quite brief. We shall, in addition, consider a number of other, more contemporary positions that borrow from the theories just cited but go off in essentially new directions, for example, the "conceptual systems" approach of Harvey, Hunt, and Schroder and the studies in cognitive growth pursued by Bruner and his associates. Our treatment will be rather narrowly focused on what the various theorists have been able to offer to the study of individuality in cognitive performance. Since a large portion of the research on cognitive controls, styles, and strategies² has been conducted within broad, theoretical frameworks, it would seem essential that we discuss these frameworks before the relevant empirical studies are considered.

Psychoanalytic Influences

We begin with a brief comparison of psychoanalytic ego psychology (e.g., Gill,

1959; Hartmann, 1958; Rapaport, 1957) and the orthodox psychoanalytic position (e.g., Fenichel, 1945; Freud, 1936). According to the latter, all cognitive functions rest upon a motivational base. It is only upon the failure of wish-fulfilling behavior ("pleasure principle") in meeting survival needs that the organism becomes cognitively attuned to its environment ("reality principle"). Even when the reality principle is dominant, however, the drives constantly press toward overt or covert expression. Hence cognition remains very much in the service of motivational and affective processes.

In contrast to the passive role assigned the ego in orthodox psychoanalytic theory, the ego psychologists have placed great emphasis upon the autonomous functions of the ego. Rapaport (1959), for example, has distinguished between primary ego structures—those that constitute the "conflict-free sphere" of the ego—and secondary ego structures—which largely comprise the defense mechanisms elucidated by Anna Freud (1946). Contained within this region are the classical cognitive functions of perception, memory, and thinking. These primary ego functions may be linked to the secondary defensive functions, however. Also, the autonomy and independence of the primary functions from drive processes are relative rather than absolute. For although the ego has been freed from dependence on sexual and aggressive instincts, *neutralized* energy from those instincts is viewed as the basic motivational source for ego function. An incisive discussion of the theoretical complexities surrounding these issues is available in R. W. White (1959).

The relation between the ego structures and drive system has been rendered most explicit by Klein (1958). He maintains that cognitive structures intervene between drives and environmental demands. It is because the cognitive structures are conceived to have a steering and modulating function in respect to both drives and situational requirements that Klein has given them the designation of "cognitive control principles." These cognitive controls are viewed as serving an accommodative function in the sense of regulating drive expression to accord with the requirements of the situation.

In sum, we note that the dominant role of

² Definitions and distinctions among these cognitive constructs will be considered later in the chapter.

drive in respect to cognition characteristic of orthodox psychoanalytic theory has been modified substantially in the theoretical position formulated by Klein and other ego-oriented analysts. Nevertheless, drives and cognitive structures in psychoanalytic ego psychology continue to be in a close interactive relation with one another. Rather unclear, however, is the issue of whether specific drives evoke particular kinds of cognitive controls. Klein (1958) suggests that there is no fixed relation between *specific* drives and cognitive structures. On the other hand, a close link is proposed between the type of task confronting the individual and the particular cognitive structures engaged by such tasks.

What are the distinguishing features of the research carried out within the foregoing theoretical framework? Its psychoanalytic roots are most evident in two types of study. First, there is the work intended to demonstrate how motivational influences are mediated by cognitive structures. Illustrative is research by Klein (1954), showing how the influence of thirst on perceptual processes is mediated by the cognitive-control principle of "constricted-flexible control" (We shall have more to say about this principle in a later section.) The second type of study (e.g., Holzman and Gardner, 1959) has probed the relations between various cognitive controls and the classical mechanisms of defense. Both of these types of research have a distinctive psychoanalytic flavor.

We shall not describe this research in detail here since none of it has employed children as subjects. This is not to imply that such work has no developmental relevance. It would be of great theoretical interest to know how drive expression is modulated by various cognitive structures as the child grows older. From the perspective of the present chapter, differences between children in the interaction of drive states and cognitive structures would also be of interest. It should be further noted that studies of children could help to clarify questions concerning the direction of causal relations between defensive structures and cognitive controls. Thus a repressive mode of coping with conflict may be shown to contribute to the development of a cognitive control of leveling (as opposed to sharpening) in regard to conflict-free perceptual and re-

call tasks. At the same time, we must recall that Rapaport (1957, 1959) considers certain cognitive structures as *primary*, that is, as outcomes of genetic, constitutional, and early learning factors, occurring prior to the development of the mechanisms of defense. But Rapaport has also asserted that the secondary autonomous ego functions, though drive-based and defensive in origin, constitute forms of cognitive structures in their own right. The empirical specification of these primary and secondary cognitive structures and their possible relations remains a task for the future.

Although the issue of the links between cognitive controls, on the one hand, and drives and defenses, on the other, is of profound theoretical importance, its complexity has necessarily limited the extent of the research effort. The major portion of the relevant research (much of it conducted at the Menninger Foundation) has been devoted to the conceptual and empirical delineation of the various cognitive controls and the examination of their relationships and patterning within individuals. The various cognitive controls are alleged to be organized as superordinate structures. Klein (1958) has described them as "cognitive styles."³ The distinction between "controls" and "styles" has not been strictly maintained, however, for one often finds the terms used interchangeably in the relevant research literature.

As defined by the Menninger group (Gardner, Holzman, Klein, Linton, and Spence, 1959), cognitive controls are stabilized ego structures that serve to coordinate "a class of adaptive intentions and a class of environmental situations." Their level of generality is presumed to be greater than that distinguishing the cognitive functions of perception, judgment, recall, etc., considered separately. Thus the same cognitive control may be manifested in tasks whose adaptive requirements lie in different cognitive domains—perception versus recall, for example. One cannot take issue with the definition of cognitive control principles provided by the Menninger group. Unfortunately, the definition provides little insight into the basis for in-

³ This approach parallels Piaget's (1957) distinction between operations and combinatorial structures.

dividual differences in the functioning of the cognitive controls, for the intentions of most subjects in regard to specific experimental tasks should be more alike than different. One must assume that all subjects *intend* to perform as best they can, unless there is independent evidence to suggest otherwise. Hence it is difficult to see how a variable of "intentions" can be useful in explaining how individuals differ in their modes of cognitive functioning.

There is, however, a more basic problem with respect to the approach of the Menninger group. With the increased concentration on the autonomous primary ego functions, the anchorage of cognitive-control research in psychoanalytic theory has been considerably loosened. The extensive program of research by Gardner and his associates into the workings of the cognitive controls alone and in combination (see Gardner, 1962, for a review) may owe a substantial debt to psychoanalytic ego psychology. It is perhaps not surprising, however, that an overarching theoretical superstructure attains limited value when a diverse array of cognitive processes are at issue. One is soon forced to deal with such processes at their own level. At this stage, the psychoanalytically inspired research of Gardner and his associates has been forced into the theoretical marketplace. The resulting conceptual and methodological controversies have been played out at a level quite far removed from general psychoanalytic concerns. This is not intended as a fundamental criticism of the work of Gardner and his colleagues. Gardner's group has been concerned with relations between cognitive controls and mechanisms of defense, a problem admirably suited for study within a psychoanalytic framework, however, they have not hesitated to lean on other theoretical systems to clarify the operation of the various cognitive control principles.

It is beyond the scope of the present chapter to review the published research by Gardner and his colleagues, for it is almost entirely based on adult samples. A large-scale, empirical study of cognitive controls in children has been carried out (Gardner and Moriarty, 1968), but only a highly tentative summary account of those findings was available in published form (Gardner, 1964) at the time this chapter was prepared.

Differentiation and Hierarchic Integration

These two concepts are fundamental to almost all theories of cognitive development. Cognitive structures in the course of development become more differentiated and hierarchically integrated, according to Lewin (e.g., 1935, 1951), Piaget (e.g., 1952, 1954), and Weiner (e.g., 1948, 1957). A similar theme can be detected in the work of Harvey, Hunt, and Schroder (1961), Birch and Lefford (1967), and Bruner, Olver, and Greenfield (1966). However, since the concepts in question are embedded within the particular theoretical systems of the authors cited, agreement among them regarding the meaning of differentiation and hierarchic integration may be more apparent than real. As we shall show, differences in conceptualization have led to diversity in the operational definition of the constructs at issue.

The Influence of Kurt Lewin. In the Lewinian formulation, differentiation has two aspects: an increasing "complexity of units" and a decreasing "interdependence of parts." The complexity of units refers to the growing variety of behavior expressed in the domains of skills, emotions, needs, knowledge, etc., the interdependence of parts is concerned with the trend away from dependence and toward independence of the various parts of the person in the way he functions. The distinction between these two aspects of differentiation is exceedingly important. Lewin actually proposed that they be given different labels. Since increasing variety involved matters of similarity and dissimilarity, he suggested that the kind of differentiation represented by "complexity of units" be designated "specialization" or "individualization," while the term "differentiation" proper be reserved for dependence-independence relations between parts of the person and between the person and the environment. Lewin's labeling recommendations have generally not been followed, however, for the term "differentiation" has until the present time been used to describe both of the processes outlined above. This is somewhat unfortunate, of course, for one tends to expect that identically labeled constructs reflect the same underlying processes. From a developmental perspective, differentiation can naturally be presumed to increase along both of the routes under discussion. From an in-

dividual-differences perspective, on the other hand, there is no guarantee that the rate at which differentiation proceeds is the same in both cases, or that the same developmental endpoint is achieved

It is a tribute to Lewin that the two major traditions of individual-differences research on processes of differentiation can be derived from the distinction under consideration. On the one hand, complexity of units with its implications for issues of similarity-dissimilarity can be considered a theoretical ancestor of Kelly's (1955) psychology of personal constructs and the derivative work on cognitive complexity by Bieri (e.g., 1961). These two authors have applied Lewinian differentiation notions (in the complexity-of-units sense) to the issue of similarity and difference in the perception of people. In Bieri's system, cognitive complexity is defined in terms of the number of dimensions generated or employed by subjects when asked to specify how familiar others (and the self) are similar to and different from each other. Lewin clearly intended, however, that differentiation also apply to the physical world. In that respect, complexity of units can be considered one of several intellectual ancestors of the burgeoning research on the cognition of similarities and differences between objects and concepts in the physical world. Much of this research has been carried out with children (e.g., Bruner, Olver, and Greenfield, 1966; Kagan, Moss, and Sigel, 1963; Wallach and Kogan, 1965), and hence falls within the purview of this chapter.

The other conceptualization of differentiation proposed by Lewin—extent of dependence-independence of parts within the person and between the person and his environment—represents a direct intellectual forbear of the extensive program of research conducted by Witkin and his associates (e.g., Witkin, Dyk, Faterson, Goodenough, and Kaip, 1962). The relevance of this research to the Lewinian formulation is highlighted by the initial conceptualization of the dimension later presumed to reflect more versus less differentiated functioning—field independence and field dependence, respectively (Witkin, Lewis, Hertzman, Machover, Meissner, and Wapner, 1954). This dimension was first assessed with a variety of perceptual tasks in which adaptive, accurate performance depended upon

the utilization of internal kinesthetic cues and the suppression of conflicting external cues. In other words, field independents had apparently succeeded in differentiating themselves from the external physical environment, whereas field dependents remained strongly susceptible to its distracting influence. Subsequent research by Witkin and his associates offered evidence for the greater internal differentiation of personality and cognitive structure in the case of field independents relative to field dependents. It must be stressed that the foregoing description of Witkin's work represents the briefest of introductions to what is undoubtedly the most massive and thorough empirical examination of a particular cognitive structure in the psychological literature. We shall have much more to say about Witkin's program of research in a subsequent section of the chapter.

In sum, we have shown how the two forms of differentiation distinguished by Lewin are reflected in two quite divergent contemporary research traditions. The exploration of the number of dimensions employed by subjects in discriminating and categorizing their social and physical world—the issue of similarities and differences—has roots in Lewin's "variety" conception of differentiation. Current research on part-whole relations in cognitive functioning—the issue of global-diffuse versus articulated-analytic functioning—can be traced to Lewinian notions of interdependence of parts in the structure of the person and the relation of that structure to the external world.

A blurring of the boundaries between a "variety" and a "part-whole" conceptualization of differentiation is revealed in the theory and research of Bieri and his associates (e.g., Bieri, Atkins, Binar, Leaman, Miller, and Tripodi, 1966). Working within the general theoretical framework of Kelly's (1955) psychology of "personal constructs" and using the Kelly Role Construct Repertory Test, Bieri (1955) derived an index of cognitive complexity representing the number of different dimensions employed by an individual in construing similarities and differences between familiar people in his social environment. The greater the level of cognitive complexity, the more multidimensional is the cognitive structure involved in the perception of other people. In its original form, the index clearly reflected the Lewinian "variety" conceptual-

ization of differentiation. More recently, however, Bieri (1966), in considering possible developmental aspects of cognitive complexity, demonstrated how that construct divides into two separate components. To the extent that individuals construe their environment on the basis of continuous dimensions rather than discrete categories (a reasonable assumption where other people constitute the stimuli), one can distinguish between the *number* of different dimensions used and the extent of gradation *within* each such dimension (the number of categories or intervals that are discriminated along the dimension). Bieri proposes that the label of "differentiation" be reserved for the number of dimensions, while gradation within dimensions be called "articulation." One might initially regret the choice of "articulation," for the part-whole form of differentiation studied by Witkin and his associates is often characterized as "field-articulation" (e.g., Gaidner et al., 1959). Yet one must acknowledge that the form of articulation posed by Bieri represents the fractionation of a whole into parts—that is, the conversion of a dichotomy into a more finely graded scale. We cannot conclude that the two forms of articulation are cut from the same cloth, for empirical research directed to that question has not yet been carried out. Bieri (1966) does, however, offer numerous suggestions on how developmental considerations can be brought to bear upon the components of cognitive complexity.

There is one further important respect in which the Bieri group has extended the Lewinian "variety" conception of differentiation. For Lewin, increasing variety in the course of development implied a more highly differentiated cognitive structure and set of behaviors. Bieri et al. (1966) have shown that the ecological characteristics of the social environment can also be described in terms of extent of differentiation. The dimensionality of stimuli and tasks can vary radically. Within such an interactional framework, one can no longer speak in unqualified terms of the greater advantage accruing to a more as opposed to a less differentiated cognitive structure. Rather, the problem becomes one of studying the effects on performance of varying degrees of discrepancy in the dimensionality of the cognitive structure and the stimulus task. As Bieri (1966) has noted, there has been essen-

tially no research of this kind within a developmental framework. Indeed, such investigations are quite infrequent even in the case of adults. The few relevant studies are discussed in the Bieri et al. (1966) volume.

Let us turn now to the matter of hierarchic integration. Lewin recognized that increasing differentiation implied decreasing "unity" of the person. Hence it made good theoretical sense to invoke a construct of hierarchic integration to put the person back together again, figuratively speaking. Lewin proposed that hierarchic integration showed a discrete, steplike increase with development. By imposing such integration upon the continually decreasing "unity" produced by differentiation, Lewin was able to show that the organizational unity of the person was essentially cyclical over the course of development. In other words, the extent of unity at a later time period might be greater or smaller than at an earlier period, for hierarchic integration is presumed to lag behind differentiation during the course of development.

While hierarchic integration is an evident logical counterpart of a "variety" or "part-whole" view of differentiation, it has been difficult to arrive at a conceptual formulation that lends itself to research on the problem in the cognitive domain. Kelly (1955), for example, distinguished superordinate from subordinate constructs in his theory, the superordinate presumably having an organizational and controlling function over the subordinate. But he did not solve the problem of devising independent measures of such higher and lower level constructs. Recent sophisticated attempts to derive independent measures of differentiation and organization are offered by Wyer (1964) and Zajonc (1960). Their efforts were only partially successful, and their procedures have not as yet been adapted for use with children.

As we noted earlier, Bieri's construct of cognitive complexity fits the Lewinian definition of differentiation rather than hierarchic integration. Further, cognitive-complexity research has been tied to the Kelly (1955) REP Test, an instrument too cumbersome for use with children. Clearly, that test will have to be modified or other techniques devised, if the important tradition of research on cognitive complexity is to be given developmental significance. Bieri (1966), taking cognizance

of these difficulties, has proposed that developmental studies be directed toward the perceptual-cognitive processes subsumed by cognitive complexity rather than toward the latter construct itself. A first and only attempt to examine cognitive complexity from this point of view is represented by the work of Signell (1966).

Three forms of complexity are distinguished in Signell's work. Two of the three are related to Brier's distinction between the variety of dimensions employed by a subject and the extent of articulation along a specific dimension. Signell describes the extent of articulation as "complexity of single concepts" and the variety of dimensions as "complexity of cognitive structure." The more complex single concept is alleged to discriminate among objects more efficiently. A dichotomous concept (e.g., nice versus not nice) has little complexity since objects (e.g., people, nations) can be classified only in one of two categories. Where a concept has several gradations, greater complexity is associated with more equal distributions of objects across the set of categories. In Signell's words, "The more complex concept has maximal power to differentiate objects" (p. 519).

Complexity of cognitive structure is derived from the Lewinian "variety" conception of differentiation. Here we are dealing with the number of relatively independent concepts or dimensions available to the individual for differentiating among objects. Signell also introduces the notion of an individual's differentiation among the objects in his environment, for the number of independent objects construed is only partially dependent upon the number of concepts available.

The third type of complexity distinguished by Signell is called "complexity of content." Whereas the two types of complexity previously described are determined on the basis of the internal relation between the elements of an individual's cognitive structure, complexity of content relies on external judgments of the diversity of concepts generated by the child. Signell employs the example of the child whose nation concepts are exclusively geographical, in contrast to the child who uses geographical, economic, and political concepts.

Thirty-six children ranging in age from 9 to 16 participated in the study. The objects of

judgment consisted of persons and nations, with half of the children assigned to the former and the remaining half to the latter. Intelligence, sex, and socioeconomic status were comparable across age groups and object content. To insure that the various procedures would be appropriate for children, only objects and concepts provided by the child were employed. These were elicited from the child through direct questioning and through the use of the triads method. Instructions for this method require the child to specify which two of three stimuli are most similar for what reason and in what respect the third stimulus is different. Striking differences in the magnitude of the correlations across the two domains were observed. For "complexity of single concepts," correlations with age were highly significant in the "person" domain, but negligible in the "nation" domain. The reversed pattern was found in regard to "complexity of cognitive structure." For "complexity of content," the correlations were again considerably higher in the "nation" domain. Thus it appears that with increasing age (in the 9 to 16 range) children develop progressively greater cognitive complexity in regard to significant people in their lives by finer differentiation of concepts already in their repertoire, rather than by acquiring a more complex array of concepts. Where nations are concerned, on the other hand, cognitive complexity shows a developmental increase through the acquisition of an array of new concepts for differentiating nations, rather than through the refined articulation of already existing concepts.

Signell accounts for the observed domain differences in terms of the contrast between "experiential" and "didactic" learning. Experiential learning is presumed to be characteristic of the way children learn about the people in their world, didactic learning is alleged to describe the more abstract, formal learning about nations—objects quite remote from the child's personal experience.⁴ According to Signell, it is in the child's interests to build workable, efficient concepts with respect to others, for these enable him to cope better with these others. No such need is presumed to underlie the child's learning about nations, with the

⁴ It is probably safe to presume that Signell's distinction would not hold for children who have traveled extensively in foreign countries.

consequence that the child assimilates new, undifferentiated concepts offered to him by adults, rather than progressively refining the concepts already in his repertoire

It is apparent from Signell's work that there are diverse forms of differentiation that can be studied within a "variety" framework. Differentiation in children of the "variety" form appears to be very much influenced by object content. W. A. Scott (1963) and Crockett (1965), in reviewing the evidence for adults, also concluded that cognitive structures vary with event domains. The issue remains highly controversial, however, for evidence in favor of generality of cognitive styles across object domains also exists (e.g., Allard and Carlson, 1963; Glixman, 1965).

Conceptual Differentiation and the Issue of Breadth of Categorization. Another descendant of a "variety" conception of differentiation is the tradition of research concerned with size of groupings in object-sorting performance. In his early work with adults, Gardner (1953) observed that subjects varied in the number of groups generated under instructions to sort common objects. Some individuals formed a large number of piles with relatively few objects in each pile, others preferred a small number of piles with a rather large number of objects in each pile. Initially characterized as the cognitive control of "equivalence range," the variable under study has more recently been designated as "conceptual differentiation" (Gardner and Schoen, 1962). The person with a high level of conceptual differentiation prefers to differentiate an array of objects into a larger number of categories; the person low in conceptual differentiation prefers a smaller number of categories.

There is a certain temptation to equate a high level of conceptual differentiation with high cognitive complexity, on the assumption that both imply the availability of a larger number of dimensions in one's conceptual repertoire. The resemblance is more apparent than real, however. Vannoy (1965) found no relation whatever between conceptual differentiation and cognitive complexity in college students. Of greater importance in the present context, however, is the meaning of conceptual differentiation from a developmental point of view. Oliver and Hornsby (in Bruner et al., 1966) have observed a strong disposition in

their youngest subjects (6-year-olds) to form pairs in an object-sorting task. About 61% of their groupings were of the pair form, in contrast to 36% for 8-year-olds and 25% for 11-year-olds. The basis for the pairwise grouping in the youngest children has been clarified by Vurpillot and Zoberman (1965). They have shown how the young child is willing to settle for a judgment of similarity when a single element of two stimuli are in correspondence. In the context of object sorting, the 6-year-old will apparently group a "house" and a "barn" because they are colored red and then ignore other objects of the same color. The remaining red objects will then be grouped pairwise on some other basis. It is quite evident, then, that young children will manifest a high level of conceptual differentiation according to Gardner's criteria.

A measure of conceptual differentiation will probably have different psychological meanings for children of different ages. Of course, Gardner and his associates were not overly concerned with developmental issues in their early work. One study involving children has been published, however (Mercado, Diaz Guerrero, and Gardner, 1963). Third- and fourth-graders of middle-class status in Guadalajara, Mexico, and Topeka, Kansas, were compared with respect to object-sorting performance. The American children manifested a higher level of conceptual differentiation than did the Mexican children. This difference was due largely to the greater willingness of the American children to leave certain objects as "singles" rather than group them with other objects. In the Gardner scoring scheme, such singles were treated as separate groups. It is difficult to justify this procedure in the light of the Messick and Kogan (1963) evidence that the number of groups formed with two or more objects is independent of the number of singles. On the basis of these methodological problems, it would certainly be premature to conclude that American children are more conceptually differentiated than their Mexican counterparts. The empirical datum of fewer singles in the Mexican sample may in fact reflect a more literal compliance to the experimental instructions, which, after all, did request that items be grouped together.

In the research of Gardner and his associates, a relationship has been postulated and

empirically confirmed in adults (Gardner and Schoen, 1962) between conceptual differentiation and breadth of categorization. A person who employs few groupings in an object-sorting task is presumed to have broad category boundaries, a person who uses many groupings is alleged to have narrow category boundaries. It is assumed that the subject in an object-sorting task is in some way concerned with the sheer number of instances to accommodate within a category. This may be so, but it is probably more reasonable to assume that the qualitative character of the categories used by those high and low in conceptual differentiation determines the number of items subsumed by them. Gardner and Schoen (1962) have, in fact, demonstrated that the person who forms fewer groupings tends to use more "abstract" categories, when abstraction is defined by an index derived from Rapaport, Gill, and Schafer (1945).

Quite clearly, an object-sorting measure is a very indirect way of assessing breadth of categorization. It can be measured much more directly when a specific category is provided and the subject is required to establish the category boundaries or "band width." Such a procedure has, in fact, been employed in several studies, some conducted with children as subjects. In the research of Wallach and Caron (1959), for example, sixth-grade children participated in a concept-attainment exercise in which they learned that certain geometric figures, distinguished by a particular size of angle, constituted a class called "poggles." This exercise was followed by a task in which a series of geometric figures, identical except for variation in acuteness of angle, were offered for judgment as "poggles" or "nonpoggles." Children displayed considerable variation in their "band width" for "poggles," some admitting many exemplars into the criterial class, others admitting few. This breadth-of-categorization measure yielded significant sex differences, with boys manifesting a broader "poggle" class.

Comparable sex differences have been observed on the Pettigrew (1958) Category Width Test, for which a children's form is available (see Wallach and Kogan, 1965). The Pettigrew instrument consists of a series of items, each of which provides the central-tendency value for a category and a set of multiple-choice alternatives. The subject's

task is to choose the most deviant member of the category at each extreme. A broad categorizer would locate the outer boundaries of the category further away from the central-tendency value than would a narrow categorizer. It should be noted that the "band-width" scores derived from the "poggles" and Pettigrew procedures were significantly correlated (r s in the 30s) in the sample of children employed in the Wallach and Caron study.

Still another procedure for assessing category breadth in children is exemplified by the dot-numerosity and line-length judgments employed in the Bruner and Tajfel (1961) work. Stimuli containing a specified number of dots and lines of a particular length were made criterial (i.e., "target" patterns). Subjects were required to judge a series of dot and line patterns on the basis of their membership or lack of membership in the "target" class. Considerable variation among children was observed in the number of patterns judged to fit the criterion. A high rate of pattern acceptance was presumed to reflect a preference for broad categorizing, a high rate of pattern rejection was considered indicative of a preference for narrow categorizing.⁵

The construct of category breadth lends itself very neatly to interpretation in strategic, as opposed to strictly stylistic terms. One can conceptualize broad "band width" as a preference for errors of inclusion over errors of exclusion. The reversed preference would characterize the child showing a narrow "band width." The child designated as favoring broad categorization has chosen to include doubtful or extreme exemplars in a category at the risk of including those that do not.

⁵ Most of the procedures used in assessing category breadth require the subject to make a judgment in a situation of response uncertainty. Therefore subjects who adopt an impulsive strategy (decide quickly) are likely to form judgments that will be classified as evidence for broad categorization. (See discussion of impulsivity later in chapter.) In addition, Gardner and Schoen (1962) have reinterpreted the Bruner-Tajfel results in terms of an acquiescent response style possibly moderated by the latter's relation to IQ. In response to the Gardner-Schoen criticism, Bruner and Tajfel (1965a) offered a counterargument, which in turn evoked a rejoinder from Gardner and Schoen (1965) and a further rejoinder from Bruner and Tajfel (1965b).

really belong. The child distinguished by narrow categorizing, in contrast, has chosen to reject doubtful or extreme exemplars at the risk of excluding those that really belong. The broad categorizer prefers errors of commission, the narrow categorizer prefers errors of omission. Rejection of an exemplar is generally an assignment to limbo in a "band-width" task where no contrast category is available. In an object-sorting task, on the other hand, rejection of an exemplar for one category or grouping will often imply candidacy for an alternative category or grouping.

On the basis of the sex difference obtained in category breadth—boys favoring broader categories—Wallach and Caron (1959) suggested that broad versus narrow categories might be indicative of cognitive risk taking versus conservatism. Subsequent research (Kogan and Wallach, 1964) into relations between cognitive and more explicit risk measures failed to confirm the Wallach-Caron proposal.

In their study of the intelligence-creativity distinction in children, Wallach and Kogan (1965) examined both of these dimensions in relation to category breadth, assessed by a children's version of Pettigrew's test. In both boys and girls, "band width" was unrelated to intelligence and positively associated with creativity. To the extent that creativity involves a capacity to emit original and unique responses, and since broad "band width" implies a tolerance for deviant instances, the relationship observed is theoretically consistent and supportive of the psychological meaning offered earlier for the construct of category breadth. It should be further noted that conceptual differentiation assessed by object sorting and category breadth assessed by the Pettigrew instrument were uncorrelated in the sample of fifth-grade boys and girls studied by Wallach and Kogan (1965). Conceptual differentiation was also unrelated to those authors' creativity indices. In sum, the kind of category breadth tapped by fineness or coarseness of grouping on an object-sorting task has a quite different meaning from the setting of category boundaries where the category at issue is explicitly provided.

The Influence of Heinz Werner. Let us turn now from the Lewinian conceptualization and the research it inspired to consider the contribution of Heinz Werner. There are

many similarities between these two major figures. Thus Werner's work is based firmly on what he described as developmental psychology's one regulative, orthogenetic principle: "wherever development occurs it proceeds from a state of relative globality and lack of differentiation to a state of increasing differentiation, articulation, and hierarchic integration" (1957, p. 126).⁶ Further reading of Werner indicates that it is in the part-whole and the subject-object interdependencies rather than in the sheer variety aspect that the resemblance with Lewin's formulation becomes manifest. Hence it is probably more than accidental that Witkin acknowledges his debt to both Werner and Lewin, whereas Bierl does not cite Werner in his published work.

Although there is much that is similar in Lewin and Werner, there is also much that is different. From the perspective of a "differentiation" construct, Werner is more explicitly committed to a developmental "stage" conception than is Lewin. The various stages are distinguished not only on the basis of part-whole and subject-object differentiation, but also in terms of the particular operations engaged at each stage. Thus development is presumed to span three levels of functioning—sensorimotor, perceptual, and conceptual—each successive level reflecting a higher degree of part-whole articulation and subject-object differentiation. At the sensorimotor level, differentiation between the person and the environment is least advanced, for cognitive functioning consists of direct, motoric commerce with the world of objects. The perceptual level is more differentiated, for the person is not in direct contact with objects but viewing them from afar, so to speak. Differentiation between subject and object is, of course, most advanced at the conceptual level, where the subject is capable of internal manipulation of symbols and abstract representations of the environment.

As Werner has noted, the "orthogenetic law, by its very nature, is an expression of unilinearity of development," (1957, p. 137).

⁶ It should be noted that, in essence, the principle is irrefutable. If, as sometimes happens, older children exhibit lesser differentiation than do younger children, this can be attributed to a hierarchic organizing principle present in older and lacking in younger children.

In other words, the developmental sequence from lesser to greater differentiation and hierarchical integration, and from sensorimotor to perceptual to conceptual functioning, is presumed universal. Despite his strict adherence to a unilinearity conception, however, Werner at the same time recognizes that there can be a multiplicity of individual developmental forms. It is necessary, for example, to reconcile a conception of physiognomic perception (e.g., the fusion of perception and feeling, as in a "gloomy landscape") as developmentally primitive and undifferentiated with the capacity for esthetic appreciation and artistic productivity in the mature adult. Evidently, operations that were initially "genetically primordial" can develop in parallel with initially more advanced operations. Werner recognizes that physiognomic perception can grow, "in certain individuals such as artists, to a level not below but on a par with that of 'geometric-technical' perception and logical discourse" (1957, p. 138).

A multilinear view of development implies that the child cannot be so easily assigned to the same developmental stage in regard to all aspects of cognitive functioning. Rather, depending upon the operations demanded by the task, one may find that the child operates at various developmental levels. Werner in fact proposes that differentiation can assume a "vertical" form, that is, individuals can vary in the number of developmentally different operations at their disposal. Associated with this idea of developmental heterogeneity is the degree of flexibility shown by the person in shifting levels in accordance with task requirements. It is noteworthy that, for Werner, shifts to lower developmental levels can be quite adaptive, if not in fact essential, for creative thinking. The more creative person, in Werner's estimation, is the one who can function at various developmental levels—in other words, is capable of progressing and regressing between more developmentally primitive and advanced operations. There is an obvious resemblance between the foregoing view of creativity and the psychoanalytic construct of "regression in the service of the ego" (Kris, 1953; Schafer, 1958). A more extended discussion of these matters is available in the chapter by Wallach in this book.

Werner's theory of multilinear development, though having strong intuitive appeal, has not

really generated much work of an empirical character. Most developmental and personality researchers are simply not accustomed to looking at a subject on the basis of his developmental heterogeneity, or the capacity to switch from one level of cognitive functioning to another. There is a strong indication in Werner's conceptualization of a preference for an intraindividual rather than an interindividual analysis of cognitive functioning. Such notions as developmental homogeneity or heterogeneity and the capacity to switch from one developmental level to another do not suggest the kinds of variables that are employed in individual-differences research of the normative type. Rather, Werner's ideas point to the study of cognitive organization within persons and hence suggest the need for ipsative analyses, which have not been particularly popular in the cognitive domain. D. M. Broverman—the psychologist most committed to an ipsative analysis of cognitive phenomena—has shown little interest in Werner's developmental ideas. In ironic contrast, Witkin has acknowledged the strong influence of Werner, but has adhered to standard interindividual analyses of Werner's concepts. It is no surprise, then, that Witkin and his associates have shed little light on Werner's conception of multilinear development.

As in the case of Lewin's conceptualization, hierarchical integration is an essential component of Werner's theory. As the individual progresses through the sensorimotor, perceptual, and conceptual phases of development, each earlier phase is presumed to become reorganized in a way that permits it to become hierarchically integrated within the subsequent, higher phase. No one can quarrel with the preceding formulation, for, quite obviously, the adult functions at all three developmental levels. The problem is, again, one of how to conceptualize hierarchical integration in operational terms. There is nothing in the Werner multilinear theory of development to help one in this regard.

It may prove useful to examine the manner in which Witkin copes with the problem. We should note first that Witkin distinguishes two aspects of integration—complexity and effectiveness. Complexity is considered to be a function of differentiation level, according to Witkin et al. (1962), for "more complex relationships among system components, and

between the system and its environment, are possible in a system with many varied components than in a system whose components are few and relatively unspecialized. Psychological development toward greater differentiation must be accompanied by successively more complex reintegrations of the system" (p. 11). Since complexity of integration is contingent upon extent of differentiation, Witkin evidently did not feel it necessary to be further concerned with that aspect of integration. At least, no attempt is made to operationalize complexity of integration in the *Psychological Differentiation* volume, even though Witkin and his associates admit that the preceding construct is only *partially* determined by level of differentiation.⁷ This implies that two children whose extent of differentiation is highly comparable can nevertheless vary considerably in complexity of integration. Though Witkin et al. (1962) do not use the term "hierarchical integration," their definition of "complexity of integration" is essentially identical to both Lewin's and Werner's definitions of "hierarchical integration." If Witkin had been able to operationalize the "complexity of integration" variable, he presumably would have done so.

Another aspect of integration—its effectiveness—offers a direct link with adjustment and pathology. These can be assessed without great difficulty, and Witkin (1965) has in fact carried out such assessments. He believes that effectiveness of integration is essentially independent of level of differentiation. Both highly differentiated individuals and those with limited differentiation are presumably capable of either adequate adjustment or pathological breakdown. However, the quality and nature of the adjustment or the pathology varies with the level of differentiation. As one might well expect, impairment in highly differentiated persons takes the form of gross separation of parts and/or complete detachment from the environment, whereas impaired individuals with low levels of differentiation manifest the dissolution of already weak boundaries between subsystems and between the self and the outside world.

⁷ As we shall note later, there is considerable controversy over the question of whether Witkin is assessing differentiation in the Werner sense. This issue is side-stepped here for the sake of the theoretical argument.

Discussing disturbances in "normal" children, Witkin et al. (1962, pp. 212–213) have maintained that global (less differentiated) children manifest "impulse control problems, a poorly developed sense of responsibility, and lack of resources and initiative," whereas analytic (more differentiated) children exhibit problems of "too rigid controls, too great emotional distance, too great an investment in intellectualization and intellectual life, sometimes with corresponding circumscription of interpersonal relations." While Witkin's efforts along the lines indicated deserve much praise, it is doubtful whether Lewin and Werner conceived of hierarchical integration exclusively in terms of adjustment and pathology. To view integration in such terms implies, to a considerable extent, a break with the universe of developmental discourse. Conceivably, pathology may be a consequence of faulty hierarchical integration. Ideally, however, we should like to assess differentiation and hierarchical integration within a common systematic framework.

Conceptual Systems Consider next the developmental theory of "conceptual systems" proposed by Harvey et al. (1961). These authors are fully committed to the proposition that development proceeds from minimal to maximal differentiation and subsequently to hierarchical integration. The consequence of this developmental process is presumed to be variation in individuals' "conceptual systems" along a dimension of "abstractness-concreteness." A conceptual system is broadly defined by Harvey et al. (1961) as "a schema that provides the basis by which the individual relates to the environmental events he experiences" (pp. 244–245). Four levels of abstractness-concreteness are distinguished, ranging from minimal differentiation at one extreme to maximal differentiation and hierarchical integration at the other. Harvey et al. (1961) have also used the term "integrative complexity" to refer to the abstract extreme.

What kind of differentiation do the creators of conceptual systems theory have in mind? The relevant writings (Harvey, 1963, 1966; Harvey, Hunt, and Schroder, 1961; Schroder, Driver, and Streufert, 1967) suggest that it is a "variety" conception in the Lewinian sense. In Harvey's (1966) words, "there seems little doubt that exposure to diversity is probably the most central prerequisite to differentiation

and integration, and hence of greater abstractness" (p. 63). One would presume that such exposure would enhance the variety of dimensions available to the person for construing his environment. There are many similarities here with the Bieri conceptualization discussed earlier. However, it will be recalled that Bieri is concerned exclusively with the cognition of other people, whereas the Harvey-Hunt-Schroder conceptualization apparently refers to cognition in general. Another difference is the treatment of hierarchic integration. Bieri's cognitive complexity construct is basically a differentiation index. For the Harvey-Hunt-Schroder team, hierarchic integration is critical to the abstractness-concreteness dimension, as reflected in the frequent use of the term *integrative* complexity in delineating the positive extreme of abstract functioning.

Despite these differences, however, the overall conceptualizations and research strategies have much in common. The most critical similarity is in the emphasis upon the match between cognitive structure and the structure of the environment. We have already mentioned Bieri's efforts to derive objective measures of environmental dimensionality. The research of the "conceptual systems group" in this regard has had the same basic aim but has been less rigorous in execution. It must be stressed, however, that the Harvey-Hunt-Schroder group has placed great stress upon the person's capacity to cope with changing environments. The recent book by Schroder, Driver, and Streufert (1967) is concerned with comparisons between abstract and concrete subjects in their responses to variations in the informational complexity of the environment.

Does conceptual systems theory adhere to a unilinear or multilinear view of development? There appears to be some ambiguity with respect to this point. On the one hand, a conceptual system is described as a highly generalized cognitive structure affecting all areas of transactions with the environment. Hunt (1966) has recently emphasized that a conceptual system has both structural and motivational aspects. At the same time, Harvey et al. (1961) have indicated that a "person need not reach the same level of abstractness of subject-object ties in all areas of development. Individuals vary considerably

in terms of the generality of their stage of functioning" (p. 111). The foregoing statement has much in common with the multilinear developmental conception favored by Werner (1957).

Thus far, we have said little about the specifically developmental aspects of conceptual systems theory. The fundamental developmental postulate in the theory is that the level of differentiation and integration attained is a function of the growing child's interactions with the principal training agents in his environment. In other words, the level of an adult's abstractness-concreteness essentially depends upon the way he was treated by parents, parent surrogates, and teachers. Thus "system I functioning" (the concrete extreme) implies a pattern of training in which the child's efforts at environmental exploration were hindered and deviation from the absolutistic standards of the training agent were not tolerated. In the case of "system II functioning," the child is presumably confronted with "laissez-faire" training practices with the consequence that he experiences more diversity than is optimal. Such persons are described as manifesting rebelliousness against the normative standards of the training agent without any corresponding development of internalized, personally derived standards. "System III functioning" is characterized by a child training pattern of overprotection and overindulgence. Exploration of both the physical and social environment is restricted, so the child presumably learns to manipulate people through dependency in order to gain his ends. Finally, for "system IV functioning" (the abstract extreme), the training pattern is presumed to be optimal in the sense that the child's exploration is not inhibited and he is free to evolve standards based on his own experience and thought.

Consider now the measurement of conceptual systems. The standard instrument has consisted of a series of sentence completion stems incorporating a variety of personal and social content. In Harvey's (1966) version of the instrument, the sentences assume the form "This I believe about _____," followed by such referents as "friendship, the American way of life, guilt, marriage, myself, religion, sin, majority opinion, people, and compromise." Another version, along with a scoring

manual, is presented in Schroder et al (1967)

In the Harvey version, the classification of an individual on the abstractness-concreteness dimension depends on the following criteria: "absolutism of his expressed beliefs, consideration of contingencies or modifying circumstances, dependency on external authorities, especially God and/or religion, frequency of trite and normative statements, degree of ethnocentrism, acceptance of socially approved modes of behavior, concern with interpersonal relationships, and the apparent simplicity-complexity of the interpretations of the world" (p. 47). Evidently, the sentence completion responses are scored for both structure and content, which is consistent with the view that conceptual systems are both cognitive and motivational.

High levels of interjudge reliability are reported in the assignment of sentence completion responses along the abstract-concrete dimension. The fundamental question, however, is the extent to which the mélange of verbal material generated by a sentence completion device is relevant to differentiation and hierarchic integration as those terms have been employed in this chapter. Both differentiation and hierarchic integration are structural in nature, and one somehow expects to see them assessed with tasks that capture the essence of such structures. Perhaps we are simply talking about "face validity." The sentence completion devices favored by the conceptual systems theorists, unfortunately, use scoring criteria which obscure the manifestation of strictly structural properties under a layer of diverse personal and social content. If conceptual systems theory is relevant to matters of differentiation and integration, the favored measuring instrument seems to be tapping those particular processes in a rather subtle and indirect way. Some of the instruments employed for "construct validation" purposes by the conceptual systems theorists would, in fact, impress many observers as supplying more direct indices of differentiation and integration than do the various sentence completion devices themselves. Of particular interest is the use of person perception procedures (Asch, 1952; Gollin, 1958) to tap the integration component of a conceptual system. Those procedures require that subjects produce brief characterizations

of two manifestly different stimulus persons, A and B. The subjects are then informed that A and B are, in reality, the same person. The task now is to integrate the prior, discrepant impressions to form a unified portrayal. Such person-perception techniques appear promising as measures of hierarchic integration tied to a "variety" type of differentiation. Unfortunately, the procedures described do not assess differentiation as such, and hence do not really demonstrate how hierarchic integration operates on previously differentiated material.

There are other shortcomings to conceptual systems theory, some acknowledged by the Harvey, Hunt, and Schroder group. Of primary importance, from the perspective of the present chapter, is the question of whether we are dealing with a theory of adult personality couched in developmental language or with a genuine developmental theory. If the latter applies, one would expect much of the research effort to concentrate on establishing empirical links between child training experiences (even if measured only by recollections of adults) and current conceptual functioning. To the extent that such connections are not demonstrated, the entire theoretical superstructure has a highly tentative quality, at least from a developmental perspective. Harvey (1966) has acknowledged that "attempts at delineating the developmental determinants of the different conceptual systems, although not extensive, have been mainly unsuccessful" (p. 62). A comparable statement may be found in Hunt (1966): "Although considerable construct validity is available on the contemporaneous effect of Conceptual Systems, there is as yet only sparse evidence directly supportive of the developmental model" (pp. 291-292).

A study by Cross (1966) contains one of the few attempts to provide an empirical test of the developmental postulates of the conceptual systems theory. Working with a sample of 377 boys from the eighth to twelfth grades, Cross selected those who scored at the extremes on a sentence-completion measure of conceptual level. The parents of the 33 boys scoring at each extreme were contacted, and an interview was requested. The final sample consisted of 54 families: 27 parents of high conceptual-level boys and 27 parents of low conceptual-level boys. Mothers

and fathers were interviewed separately. Seven basic questions were directed to the parents. These concerned matters of discipline, standards, differences of opinion, reaction to criticism from the child, and desired learning experiences for the child. The questions were intended to assess the "unilaterality-interdependence" of the parent-child relation. A five-point scale was employed, with a "one" assigned to the case of complete parental control (high unilaterality) and a "five" assigned where the "parent influences only through dissemination of factual information" (high interdependence). In addition to the interview, a shortened form of the PARI (Schaefer and Bell, 1958) was administered to the parents to provide a measure of parental authoritarianism and warmth.

Both mothers and fathers of high conceptual-level boys were more "interdependent" (less "unilateral") than were the parents of the low conceptual-level boys. With respect to the authoritarianism dimension from the PARI, nonauthoritarian parents (particularly mothers) were linked to boys of high conceptual level. Such boys also had fathers who were more "intrinsically accepting" relative to the fathers of boys of low conceptual level.

The results are supportive of the developmental postulates of the Harvey et al. (1961) theory. Parents who grant greater autonomy to the child, tolerate his point of view, and encourage diversity apparently produce sons who yield high conceptual-level scores on the instruments devised by the Harvey, Hunt, and Schroder group. There is one serious difficulty with the Cross study, however. In the course of interviewing the parents, the interviewer can probably infer the conceptual level of the son, which could well bias the rating assigned to the parents. Since a global judgment of parental unilaterality-interdependence was employed, the danger of such bias is particularly acute. Also disturbing is Cross' failure to specify whether the interviewer was or was not informed of the extreme group to which the son belonged. If such information was in the possession of the interviewer before the session with the parents, the outcomes of the interview portion of the study would be of little scientific value. Of course, Cross' PARI data, which were not susceptible to biasing, tended to be consistent with the interview findings.

With the Cross research as an impetus, we can probably look forward to further empirical research specifically aimed at the developmental propositions of the theory. Unless these propositions can be verified, the developmental aspects of the theory will obviously have to be abandoned or drastically modified.

A promising direction for future developmental research within the conceptual systems framework is contained in a recent contribution by Hunt (1966). Given that conceptual systems are presumed to represent the "precipitates" of past encounters with training agents, Hunt has been attempting to enhance individuals' levels of abstractness by means of planned educational experiences. Research of this type can best be conducted with children, on the presumption that their level of cognitive functioning is still susceptible to change. The success or failure of such experimental interventions will certainly provide further clues concerning the viability of the developmentally relevant, theoretical propositions.

Conceptual Systems and the Piagetian Construct of "Decentering." Ideas drawn from other developmental theorists are woven into the rather complicated (if not cumbersome) conceptual systems fabric. Thus abstractness-concreteness is sometimes characterized in terms highly reminiscent of Piaget's egocentrism-relativism dimension—the disposition to view the environment exclusively from one's own point of view without any awareness of doing so. Whereas egocentrism for Piaget (1926, 1954) is a developmental stage and not a way of characterizing persons, efforts have been made to distinguish among children in their degrees of egocentrism. This is the closest that psychologists have come to the empirical study of individual differences in differentiation within Piaget's system.

The egocentrism-relativism dimension can be subsumed under the more general construct of "decentering"—the ability to shift or decenter from one aspect of a situation to another, an ability that emerges when abstract conceptual thought has gained ascendancy over sensory and perceptual processes in the child's commerce with his environment. The Piagetian notion of coping with one's environment through decentering mechanisms has evoked a responsive chord in investigators.

assessing conceptual level within the Harvey-Hunt-Schroder framework. Not surprisingly, investigators in this tradition have incorporated Piaget-inspired tasks in their assessment program.

A favored instrument has been the role-taking task (RTT) developed by Feffer (1959). First applied to adults, the RTT is a projective task derived from Schneiderman's Make-a-Picture-Story (MAPS). The test materials consist of several background scenes and a variety of human and animal figures. The subject is required to tell a story, based on a particular background scene, that uses at least three of the available figures. Then he is asked to retell the story from the point of view of each of the three figures. In other words, the subject must decenter and adopt the perspective of others while remaining consistent with his previous stories.

Of particular interest is the Feffer and Gourevitch (1960) research on a sample of boys in the 6 to 13 age range. In addition to the RTT, the boys were administered four traditional, Piaget-type cognitive tasks. A correct solution on these tasks required the balanced decentering typical of conceptual thought. Consistent with expectations, the older children performed better than the younger on both RTT and the strictly cognitive tasks. The relation between performance in the two domains was significant, with both age and intelligence controlled. This outcome should have come as no great surprise to Piaget, who has always maintained that the same cognitive principles apply in both the impersonal and personal world of the child. Feffer and Gourevitch suggest that decentering in the child's physical world might precede the ability to take the perspective of others in the social world. Research of a longitudinal character would be required to settle the issue. Note, finally, that Sullivan and Hunt (1967) did not find a relation in 7- to 11-year-olds between Feffer's RTT and a Piaget-type task based on shifting spatial perspectives. Evidently the RTT does not relate to all Piaget-type tasks with decentering properties.

An explicit bridge between Piaget's decentering construct and conceptual systems theory (Harvey et al., 1961) can be found in Wolfe (1963). System III and IV functioning implies a level of differentiation between self

and others where one should prove able to adopt the perspective of another person. Accordingly, Wolfe examined the extent of association between a conceptual systems index and Feffer's RTT. Gollin's (1958) Impression Formation Task was also employed. The male subjects of the study ranged from age 10 to 21 and were enrolled in grades 6 to 12.

With age and intelligence held constant, conceptual level was significantly related to role-taking ability. Rather disturbing, however, was the evidence that verbal productivity (number of words) on the RTT was significantly correlated with the RTT score ($r = .61$). Though it is unlikely that verbal productivity could mediate the relation between the RTT and Piaget-type cognitive tasks, the possibility of such mediation should certainly be examined.

The Research of Bruner and His Associates. We consider, finally, the very important, recent contribution of the Harvard Center for Cognitive Studies (Bruner, Olver, and Greenfield, 1966). Although the examination of individual differences has not been the central focus of the work of Bruner and his associates, the implications of that work for individuality of cognitive functioning are strikingly clear. Such implications were already apparent in the earlier work on concept attainment (Bruner, Goodnow, and Austin, 1956), where young adult subjects were distinguished on the basis of preferred strategies of information seeking and problem solving. This conceptual and methodological orientation has been extended and elaborated in the more recent research with children. There are numerous instances in *Studies in Cognitive Growth* where differences among children at a specific age level are discussed (especially as they relate to the influence of cultural differences). One also finds occasional tests of the children's consistency of cognitive functioning across diverse tasks. There is even a detailed description of an unpublished study (Kuhlman, 1960) in which children were classified on the basis of a theoretically relevant cognitive typology. Note also should be made of the diverse research procedures employed by the Bruner group. Many of these procedures would be admirably suited for the study of individual differences in the cognitive functioning of children.

The developmental sequence of differentia-

tion and hierarchic integration is not so explicitly stated in the research of Bruner and his associates as in the writings of the other developmentalists considered thus far. In fact, references to differentiation as such are quite rare in Bruner et al. (1966)—reflected by the term's absence in the book's index. On the other hand, there is frequent reference to "hierarchical thought structures" throughout the book. As we shall see, however, the research described in *Studies in Cognitive Growth* is highly relevant to both differentiation and hierarchic integration, and, in fact, offers operational indices of both of those constructs within a common frame of reference.

The fundamental developmental theme in Bruner et al. (1966) concerns the changes in the child's favored mode of representation of his world as he grows older. The term "enactive" is used to describe the very young child's dependence upon sensorimotor activity in the representational process. With growth, the emphasis shifts to the "ikonic" mode. The child can now represent the world in the form of an image or schema that is relatively independent of motor action. Cognitive growth culminates with the achievement of the "symbolic" mode. In short, the child acquires conceptual structures that free him from undue dependence upon the way things look and permit the kind of internal manipulation of symbols characteristic of abstract and logical thought. This schematic outline hardly begins to do justice to the richness and complexity of the conceptualization. But, to reiterate, it is not the goal of the present chapter to review the various theories of cognitive development, but rather to consider whatever implications such theories may have for individuality of cognitive functioning in children.

The enactive-ikonic-symbolic sequence parallels the developmental sequence described by both Piaget and Werner. Although *Studies in Cognitive Growth* does not offer an explicit commitment to multilinear development and individuality as propounded by Werner in his 1957 paper, one has the impression that the Bruner group was compelled to accept multilinearity of development on the basis of the empirical outcomes of their cross-cultural studies. The transition from a perceptual to a conceptual mode of cognizing, so typical of children in Western civilization, was discovered to be much less characteristic of chil-

dren from underdeveloped areas of the world who had not been exposed to Western types of schooling. For these children, development often reaches an end product of finely differentiated perception rather than abstract conceptual thinking. Analogous results have been reported with respect to differences between middle-class American children and so-called "culturally deprived" minorities. There is, in other words, more than a single developmental path. The sensorimotor-perceptual-conceptual sequence may well have a biological basis, but cultural influences can evidently bring about substantial variation on the general theme. Once cultural influences are admitted as a determining factor in cognitive development, the path has been thrown open to the study of subcultural and individual differences as well. One finds occasional hints in the recent Bruner et al. work of important individual variations in cognitive functioning outside of the context of basic cultural differences. It is also of particular interest to note that Bruner dissociates himself from any value judgment regarding the superiority of one particular cognitive mode over another. There is the recognition that abstract conceptual thought is not the sole, or even the ideal vehicle for art and poetry.

Let us now return to the issues of differentiation and hierarchic integration. Much of *Studies in Cognitive Growth* concerns the child's apprehension of identity and equivalence—that is, his manner of coping with similarity and difference. Bruner offers much evidence in support of the fundamental proposition that development proceeds from global and diffuse functioning, through differentiation, to an end product of hierarchic integration. Using children varying in age from approximately 4 to 12, the Bruner group has been able to examine the preceding three phases of the developmental process within the framework of a single task. Results obtained with one such task, developed by Olver and Hornsby, will be described in some detail later in this chapter. In contrast to this accomplishment of the Bruner group, we note that hierarchic integration is an important construct in the work of both Witkin and Bieri, yet neither has had much success in operationalizing the construct in a way that represents a higher level of functioning than differentiation. Harvey, Hunt, and Schroder

claim that they are able to assess all three developmental levels with the identical instrument, but the relevance of such assessment to cognitive functioning in children at various age levels has not yet been conclusively demonstrated

Bruner's conceptualization of differentiation can be distinguished from that of Lewin and Werner. For the latter authors, differentiation refers to cognitive and personality processes closely linked to the self system. Bruner's use of this term is confined to words and concepts largely extrinsic to the self. As a result, he views differentiation as characteristic of a relatively primitive level of cognitive functioning. Children at a relatively young age are able to focus on small details in perceptual tasks, to distribute objects across a variety of categories, and to generate numerous hypotheses in information-seeking tasks. Such performance turns out to be less than adaptive, however, for the tasks in question demand the application of hierarchical thought structures for effective performance, and these the younger children do not yet possess.

The contrast between differentiation and hierarchic integration in Bruner et al. (1966) is best illustrated in the chapters on "culture and equivalence" authored by Maccoby and Modiano and by Greenfield, Reich, and Olver. In the former chapter, Mexican children from a village and from a city were compared with one another and with New England children on the Olver and Hornsby (1966) task. This task consisted of a set of items—banana, peach, potato, meat, milk, water, air, germs, stones—presented one at a time with instructions to indicate the way in which each succeeding item was different from and similar to the items that preceded it.

The findings of major relevance here concern the sharp distinction (increasing with age) between the children from a Mexican village and the children from the urban areas of Mexico City and Boston in the capacity to analyze and synthesize, that is, cope with differences and similarities on the Olver-Hornsby task. At the youngest age levels (6 to 8), there were few rural-urban differences. Children of that age were better able to discriminate differences accurately than to synthesize accurately. With development, the urban children made the leap toward ade-

quate synthesizing ability, an advance that eluded the older village child. This village child, in contrast, followed the developmental path of progressively finer, subtler discrimination of differences.

Synthesis, or the recognition of similarities in the Olver-Hornsby procedure, requires that the child go beyond the external, perceptual attributes of objects to a higher-order abstraction. This jump from the perceptual to the conceptual proved much more difficult for the unschooled village child than for the child attending urban schools. It is our view that the accurate discrimination of differences can be considered an index of differentiation, the accurate apprehension of similarities can be considered an index of hierarchic integration. Differentiation requires that the child have reached the perceptual or "iconic" stage of development, hierarchic integration is achieved only when the child has progressed to the conceptual or symbolic level. Of course, the foregoing operational definitions do not exhaust the possible theoretical meanings of the constructs of differentiation and hierarchic integration.

Research reported in the chapter by Greenfield, Reich, and Olver confirms and extends the findings obtained by Maccoby and Modiano. The former authors studied Eskimo children in Alaska and Wolof children in Senegal. As with the Mexican village children, the Eskimo child is slower than the white urban child in making the transition from the perceptual to the conceptual level, though the older Eskimo child does eventually provide as many superordinate constructs as his urban age peer.

The work of Greenfield et al. in Senegal, employing Wolof children from both the bush and the school as well as French children, demonstrates the manner in which the processes of differentiation and hierarchic integration are linked to the differential usage of superordinate constructs by speakers of the Wolof and French languages. The Wolof language, according to Greenfield et al., is at a single level of generality and hence adequate for differentiating between objects, synthesis depends on superordinate terms, however, and these cannot readily be generated within the structure of the Wolof lexicon. It is not surprising, then, that bilingual Wolof children show considerably more hierarchic

integration in equivalence judgments when employing French as opposed to their native Wolof tongue. On the other hand, it must be noted that the use of French and Wolof is confounded with schooling and lack of schooling, so that differences in hierarchic integration could be as much a function of Western-oriented education as of the lexical structure of the French and Wolof tongues.

The evidence for processes akin to differentiation and hierarchic integration is not confined to the study of equivalence in Bruner et al (1966). The work on strategies of information seeking (the 20-questions game) and on perceptual recognition by Mosher and Hornsby and by Potter, respectively, has yielded results consistent with the data on equivalence. In the information-seeking context of the 20-questions game, younger children emitted a discrete series of unconnected hypotheses. Older children, by contrast, asked questions derived from a hierarchic structure. General constraint-seeking questions preceded more specific hypothesis-testing questions in an orderly, efficient sequence. Comparable effects were observed in the domain of perceptual recognition (a scene, initially out of focus, gradually moving into focus). The youngest children offered an unrelated series of hypotheses as to the nature of the viewed picture. Older children were better able to integrate the stimulus features and their memory store in a cyclical, hypothesis-testing manner. It should be noted, finally, that the primacy of differentiation over hierarchic integration in regard to similarity-difference judgments was also found to prevail in Piaget-type tasks. Bruner and Kenney, reporting on conservation research in Bruner et al (1966), claim that 41% of their 3-year-olds spontaneously reported a *difference* between two beakers when asked how the two beakers were *alike*. Thus conservation phenomena appear to have much in common with equivalence rules. As Bruner et al (1966) have asserted: "Learning to recognize the underlying respect in which two quantities are alike (though they appear different) is the same task as learning how a bell and a horn are alike—or a man and an animal" (p. 325).

It should be reiterated that the treatment of both differentiation and hierarchic integration in the research of Bruner and his asso-

ciates has proceeded within a developmental, not an individual-differences framework. One finds occasional reference, however, to tests of consistency across different kinds of tasks—for example, equivalence versus information seeking. This certainly represents a gesture in the direction of an examination of individual consistency and difference, and it opens up the empirical possibility of placing children of comparable age along one or more dimensions of differentiation and hierarchic integration.

Summary. As can be seen, the same limited set of constructs—differentiation and hierarchic integration—has supplied the framework for a variety of developmental studies of cognition. A major difficulty with these constructs is their conceptual ambiguity. Different investigators have used them in profoundly different ways. In addition, most researchers have not provided a truly adequate operational base for these constructs, quite apart from the theoretical meaning attributed to them. As a result, differentiation and hierarchic integration have not been as useful as they might conceivably have been. For this reason, a large portion of the empirical research on individual differences in children's cognition has been conducted outside the framework of a theory of differentiation and hierarchic integration. This will be reflected in the limited application of these constructs in most of the research described in the subsequent sections.

THE PROBLEM-SOLVING PROCESS AS AN APPROACH TO THE STUDY OF INDIVIDUAL DIFFERENCES

There are three ways to structure the discussion of individual differences in cognition—by method, theory, or description. We have chosen the last. More specifically, we shall consider the topic from the point of view of the problem-solving process in a scheme that approximates the chronology of that process. The strategy was derived from two premises—more research has been concerned with directed problem solving than with undirected thought, such as free association or reverie, and tracing the chronology of the problem-solving process seems to have heuristic value. This section shall consider, in sequence, the separate processes of encoding, memory,

generation of hypotheses, evaluation, and deduction. There will also be a discussion of public report. In all cases, the text shall focus on sources of individual differences in these functions. The choice of these functions does not imply that they are the only sources of variation in cognition. These domains have been the areas explored most extensively. Nor are these choices to be interpreted as implying a view of cognition as a completely linear chain of events. We hope, however, that the categories suggested above represent a useful way to analyze the fluidity of thought.

Processes of encoding, memory, hypothesis generation, evaluation, and deduction bear some relation to the cognitive controls originally suggested by Gardner et al. (1959) and studied in children by Santostefano (1964a, 1964b) and Santostefano and Paley (1964). Gardner, Santostefano, and their associates postulate a set of cognitive controls whose aim or purpose is to assist the individual's adaptation to the environment. They include focal attention, field articulation, leveling-sharpening, and equivalence range. It is assumed that there are consistent individual differences in each of these dimensions.

Differences in focal attention refer to tendencies to scan an object passively in contrast to an active, vigorous, and more purposive study of the environment. Differences in field articulation refer to selectivity of attention, that is, the ability to attend selectively to the salient or figural aspect of a context. This dimension is related to, but certainly not identical with, Witkin's construct of field independence. Differences in leveling-sharpening refer to the ability to hold recent events in memory so that comparisons between current and immediately preceding inputs can be made accurately. Equivalence range refers to the category width preferred by a person—the breadth of the category boundaries for particular classes of events.

There is considerable similarity between the cognitive process of encoding and the controls of focal attention and field articulation, that is, between hypothesis generation and equivalence range. The authors have chosen to structure this section around the more traditional categories for several reasons. First, such a strategy allows easier assimilation of the existing empirical data that are developmental in nature. Second, the construct of

style or control is less independent of value considerations than such processes as encoding, memory, or hypothesis generation. The dimensions of field independence versus dependence, constricted versus flexible control, and complexity versus simplicity leave few doubts regarding the positively valued poles. When these value distinctions are associated with veridical or accurate performance, in contrast to nonveridical or inaccurate performance, the distinction between cognitive style constructs and abilities becomes blurred. This does not necessarily mean that the stylistic dimensions are isomorphic with the "simple and sovereign" IQ. Rather, these dimensions will be selectively related to certain abilities but unrelated to others (Gardner, Jackson, and Messick, 1960). The link between stylistic variables and the traditional separate *abilities* is a delicate and controversial issue to which we shall devote considerable attention.

Finally, the decision to organize the discussion around the more traditional cognitive categories does not require a judgment as to the motivational bases for these cognitive processes. Cognitive controls, as conceived by Gardner and Santostefano, are viewed as instrumental processes serving ego motives and are part of motivational and defensive structures. Although selectivity of attention, memory, and categorization strategies can and do serve motivational forces on occasion, it is not clear whether this is always the case. More important, there is honest disagreement as to the specific motives served. The cognitive controls derive directly from a psychoanalytic conception of motivational structure and there is some profit in examining cognition initially from a motivationally more neutral stance.

We shall now consider the separate processes of encoding, memory, hypothesis generation, evaluation, deduction, and public report. Since a variety of theoretical forces have spawned the relevant empirical investigations, we shall attempt to blend the available ideas and data into a reasonably harmonious form.

Encoding (or Decoding)

The translation of information is the first process in the cognitive sequence. Guilford (1956, 1959) has labeled this process *recognition* in his systematic description of intel-

lectual processes. But encoding is more than merely labeling. Encoding involves selective attention to one event rather than another, and selectivity of attention is partly a function of the individual's adaptation level. The reader is referred to Neisser (1967) for an imaginative summary of research on perceptual processing in adults. The nature of the decoded product depends, first, on the nature of the information and on the availability of cognitive units to process the material. There are dramatic differences among children in available language resources for labeling events (Bernstein, 1961, Hess and Shipman, 1965) and correspondingly dramatic differences in quality of product.

The nature of the encoded event is also a function of the preference for perceptual analysis. Existing data suggest, for example, that girls may be less likely than boys to analyze a geometric design into its component parts (Kagan, Rosman, Day, Albert, and Phillips, 1964, Witkin et al., 1962). Similarly, younger children may be less likely to attend to component parts of an object than older children (Lee, Kagan, and Rabson, 1963). Elkind, Koegler, and Go (1964) showed pictures to 195 children (aged 4 to 9 years) and asked the children to describe the stimuli. There was a regular increase with age in the proportion of children who described both parts and wholes, with the brighter children most likely to describe parts rather than wholes.

A recent study of social class differences in encoding strategies in 10-year-olds revealed that middle-class children were more likely to use descriptive and analytic language when asked to differentiate a design or face from a group of similar stimuli. Specifically, the child was shown an array of five designs (or faces) plus one cue stimulus and asked to describe the cue stimulus so that another child of his age could easily pick it out from the array. Middle-class boys and girls were not only more analytic and descriptive in their encoding of the visual stimuli in contrast to the lower-class children who were global, but they were also better able to decode (understand) the analytic descriptions of their middle-class peers. "The style of encoding in which each class was most successful as decoder was the style used most frequently by

that class in encoding" (Heider, 1968, p. 104).

Although the corpus of research on set and recognition will not be reviewed here, it emphasizes the proposition that the expectations of the adult direct his interpretations of experience (see Blum, 1957, Jones and Bruner, 1954, Petigrew, Allport, and Barnett, 1958, Tajfel, 1957). Recent research with children on the role of set in perception (Maccoby, 1967, Maccoby and Konrad, 1967) demonstrated that preparatory set for auditory stimuli was generally an advantage for children if the signal was given before a stimulus, especially if the information was complex. In these experiments, a child (aged 5 to 14 years) is presented two tape recorded word messages simultaneously, one in a man's voice and one in a woman's voice, played over external speakers. After the speaking has stopped, the child must report the message spoken by one of the voices. The results are relatively clear. With age, the children are better able to report the voice they were requested to report, and they report fewer words spoken by the voice they were instructed to ignore. It is important to determine whether this is a difference in perception or in performance. Is the age difference produced because the young child cannot shut out the unwanted voice or because he cannot inhibit reporting the unwanted information? This issue is still not resolved. As might be expected, the greater the difference in familiarity of the words spoken by the two voices, the better able the child is to report only the instructed voice. Distinctiveness of the signal aids selected recall, and meaning lends distinctiveness to a signal. Maccoby (in press) concludes:

It is not especially useful to think of the deficit in terms of the child's having a more limited information processing capacity or memory storage capacity in the usual meaning of these terms. Rather the problem would seem to be that the capacity the young child does have is not effectively employed. It is the effect of the unwanted material on the perception of the wanted material that is the heart of the problem.

It is possible that the perceptions of the children are accurate, but their report is defi-

cient During the act of reporting, the young child may be unable to keep the signals separate Thus interference may occur in the act of reporting and destroy the quality of performance This hypothesis could be tested by playing simultaneous messages but not asking the child to report what he heard Rather, the child should be asked to point to pictures that illustrate each of the messages If the children were accurate in this task, it would be reasonable to conclude that the problem is not in the perceptual but in the reporting phase

Constricted versus Flexible Control These terms were used first by Klein (1954) to describe the extent to which subjects were susceptible to distraction and cognitive interference in tasks containing conflicting cues The Stroop (1935) Color-Word Interference Test has been the favored instrument for assessing constricted versus flexible control

In the traditional Stroop test, the subject first reads color words to provide an index of reading speed, then names the colors in a series of colored patches to provide an index of speed of naming colors, and finally names the colors of a set of color words printed in incongruous colors (e.g., the word "red" printed in blue) to provide an index of susceptibility to interference Ratio or difference scores are generally used, and sometimes reading speed and speed of naming colors are regressed out of the interference score The various scoring formulas are available in an exhaustive review of research with the Stroop test published by Jensen and Rohwer (1966)

Since word reading habits are not well established in young children, Santostefano and Paley (1964) devised a Fruit-Distraction Test as a reasonable equivalent to the Stroop The test consisted of two cards, one of which contained pictures of fruits appropriately colored The second card was identical to the first, but, in addition, a variety of food and nonfood objects were drawn adjacent to the relevant fruits The child's task was to report orally the colors of the fruits on the first and second cards The difference in performance (reading speed and errors) between the first and second cards provided an index of the degree to which the child was disrupted by the intrusive information on the second card Also obtained was a measure of the number of intrusive stimuli recalled

Significant age differences in interference were obtained for reading speed The oldest children were apparently least distracted by the intrusive stimuli, whereas the youngest children were most distracted Reading errors did not yield significant age effects With respect to recall of the intrusive information, significant age differences were found for the number of intrusive food stimuli remembered—the youngest children showed the best recall, the oldest children showed the worst The data on reading speed and number of intrusive stimuli recalled are consistent, of course It appears that the younger children are less able than the older to avoid attending to the distracting information

In sum, younger children are more vulnerable to interference in situations where wanted and unwanted signals—from the experimenter's point of view—are presented simultaneously The interpretation of these differences is still unclear, however

Encoding across Sensory Modalities Birch and his colleagues (Birch and Belmont, 1964, 1965, Birch and Lefford, 1963, 1967) emphasize developmental differences in the interpretation and integration of sensory inputs from various sense modalities Birch assumes that development is accompanied by (1) hierarchical shifts in the locus of control of actions (e.g., tactile to visual control of a particular motor pattern), (2) integration across sensory modalities, and (3) differentiation within modalities In a classic study derived from this point of view, 145 children (5 to 11 years of age) had to make judgments about the equivalence of two geometric forms in a situation in which a form presented in one sensory system (the standard) was compared with a form presented in another sensory system (the variable) A *visual* standard was compared with a series of forms presented haptically or kinesthetically, a haptically presented form was compared with a kinesthetically presented variable The stimuli were eight blocks from the Sequon Form Board, and paired stimuli were presented to each child The first member of a pair was presented in either the visual or the haptic mode The second member of the pair was either haptic or kinesthetic if the standard was visual, and kinesthetic if the standard was haptic Some of the forms were identical with the standard, some were different from

the standard. The child had to say whether the comparison form was the *same* as or *different* from the standard.

Errors for all three classes of comparisons decreased with age. The visual-haptic comparison was easiest for all children, the haptic-kinesthetic and visual-kinesthetic comparisons were much more difficult, with the latter being the most difficult. By 8 to 9 years of age most children were performing very well, differential difficulty of the three classes of comparisons was most apparent over the age range 5 to 7 years. The intercorrelations of quality of performance across the three types of comparison were close to zero at 5 years of age, but increased with age, approaching .70 by the time the children were 7 years old. No major sex differences were found.

Birch suggests that visual-haptic integration has its most rapid period of growth during the age span 3 to 4 years, whereas visual-kinesthetic and haptic-kinesthetic integration grow during the period 6 to 8 years of age. The flavor of Birch's discussion emphasizes a biological basis to these changes, and this is a plausible interpretative stance. It is also possible, however, to view these data as studies in decision making. The decrease in error scores over age could be a partial function of longer decision times. The issue of individual differences in decision time—the reflection-impulsivity dimension—will be considered later in the chapter.

Visual-haptic comparisons may be easy because these comparisons are made more often in the environment, and the child has had extensive experience in this integration. If children were reared in an environment in which visual-kinesthetic judgments were frequently required, there might be a reversal of these trends. This supposition finds support in a comparison of American and Nigerian subjects on the Witkin versions of the Rod-and-Frame and Embedded Figures Tests (Wober, 1967). The Nigerian subjects were more field independent than Americans (i.e., had lower error scores) on the Rod-and-Frame Test where attention to proprioceptive cues is critical. Moreover, there was a negligible correlation for the Nigerians between performance on the Rod-and-Frame and on the Embedded Figures Tests ($r = .21$), whereas among Americans the correlations were highly positive, ranging from .5 to .8.

Wober argues effectively that the Nigerian subjects grow up in a culture that emphasizes analysis of proprioceptive cues and minimizes the value of visual analysis. He suggests "The prevailing patterns of childhood intake and proliferation of information from the various sense modalities differ according to culture" (Wober, 1967, p. 31).

It is therefore not beyond reason to suggest that the relative difficulty of visual-kinesthetic over visual-haptic integration reported by Birch and Lefford might be reversed if American children's life experiences required visual-kinesthetic comparisons. Cognitive functioning appears to be a most plastic enterprise, and generalizations about universalistic hierarchies or stages of development should be tempered until adequate cross-cultural data are examined.

Encoding and Attention The encoding process touches directly the issue of individual differences in selectivity of attention—selective focusing on one particular aspect of an array or event rather than another, attention that is maintained versus attention that is shortlived. Directed attention refers to selective focusing—the selection of one aspect from the available field over another, and the inhibition of urges to turn from the field of focus. Directed attention is relatively free from interference. One can define selectivity of attention (or focused attention) as the degree to which thresholds are selectively lowered for one class of stimuli relative to others. Attention is focused when the profile of thresholds for an orientation response to classes of stimuli forms a "V," that is, when the threshold for a given stimulus is low, and thresholds for other stimuli are high. Attention is diffuse when the function relating orientation threshold to the envelope of immediate stimuli is horizontal, that is, when the thresholds for orientation for many classes of immediate stimuli are the same.

Broadbent regards selectivity of attention as the result of the action of sets of filters. The central nervous system decides which information arriving at the eyes, ears, or skin is to be admitted through the filters. Only the information that passes is processed (Broadbent, 1958). Broadbent's experiments tend to support this hypothesis, and he has suggested that it is difficult to attend to more than one input channel at a time. It is possible that a

major difference between younger and older children is that the younger cannot shift focus of attention rapidly, whereas an adolescent can redirect focus quickly, although the number of channels that can be simultaneously monitored may not change much with age. If this were true it would suggest, albeit at a conjectural level, that the old saw about the "booming, buzzing confusion" of the world of the infant is in error. If the infant does not shift focus quickly and attends to one channel at a time, then he may not hear the television while he is watching his fingers, not see the colored lights on the Christmas tree while he is listening to his mother, not feel the jostling of the crib while he is feeling the discomfort of hunger contractions.

Measurement of Attention in Children Although this chapter is not primarily concerned with methodology, it is appropriate to consider, if only briefly, procedures for assessing aspects of attentional processes. As indicated earlier, attention refers to the differential selectivity of thresholds to a range of stimuli in the child's life space. As that profile approaches a peaked "V," attention becomes more selective. Under those conditions, respiration becomes more regular and heart rate decreases and becomes less variable (Lacey, 1959, 1967). Moreover, the cardiac changes are not necessarily completely dependent upon changes in respiration (Biener and Hothersall, 1967) and may be concomitants of decreased somatomotor activity (Obrist and Webb, 1967). These variables are some of the indexes one can quantify during periods of sustained and selective attention to an external stimulus.

The state of concentration is accompanied by different patterns. The child who is concentrating is selectively attending to internal images or thoughts, and wishes to insulate himself against external stimulation. The profile of reactions to this class of selected investment of attention includes an increase in cardiac rate and variability, dilation of the pupil, and a decrease in skin resistance (Kahneman, Tursky, Shapiro, and Crider, 1969).

The peripheral responses under selective attention to external stimuli are different from the pattern of responses shown under concentration. It is possible that subtle changes in the profile of muscle tone in various parts

of the body are critical mediators of the differences in autonomic responses described above (see Obrist and Webb, 1967). In any case, the pattern of autonomic responses can be helpful in investigation of these attentional states. Kahneman has demonstrated that the degree of dilation of the pupil covaries, in almost a linear fashion, with the difficulty of the mental task being presented (Kahneman and Beatty, 1966, 1967) and he suggests that the critical psychological variable is attentional commitment (i.e., the degree to which the attentional apparatus is committed to working on the problem at hand). The more difficult the problem, the more imperative it is that the attentional system be totally committed to the problem. It appears that sensitive combination of somatic and autonomic reactions will be useful in monitoring the fragile phenomenon of attention. Fortunately, children do not object to these procedures, and the availability of telemetric devices does away with the necessity of constraining the child in one place.

The Bases for Attention in Infancy The bases for orientation, selectivity, and maintenance of attention are crucial for understanding cognitive processes. We shall consider briefly these bases for attention as they emerge in the first two years.

The earliest determinant of attention, from an ontogenetic point of view, is high rate of change in the physical parameters of a stimulus. Lights that blink on and off are more likely to capture the newborn's attention than a steady light source. Intermittent tones are more attention getting than continuous ones. Visual events with high black-white contour contrast possess more power to recruit sustained attention than stimuli with minimal contour contrast (Fantz and Nevis, 1967, Salapatek and Kessen, 1966). These conditions are naturally distinctive. They seem to elicit the infant's attention without prior learning. These stimulus conditions dominate the recruitment of attention during the first 10 to 12 weeks.

A second class of conditions that produces distinctiveness is the product of experience and involves the relation between external events and the child's acquired schema for that event. The schema is defined as a hierarchical arrangement of distinctive elements of an event. The schema is not a replica of

the event but a schematic or partial representation. Selectivity and maintenance of attention appear to be curvilinearly related to the degree to which the features of an event are a distortion or discrepancy from an established schema. A child gives maximal attention to an event that is a moderate deviation from the distinctive features of his schema. The discrepant stimulus event is to be distinguished from a novel event. A novel stimulus is one that has minimal similarity or relation to any schema the child possesses. Thus the random shape or meaningless design is a novel event to a 6-month-old infant. A picture of a face with only one eye, however, is a discrepant event. A 4-month-old infant will look longer at a photograph of a face—regular or disfigured—than he will at a randomly generated figure with a high degree of black-white contrast (McCall and Kagan, 1967). This difference does not appear to be present at birth (Fantz and Nevis, 1967), the child must develop some primitive schema for a human face before the representations contained in the achromatic faces gain their attention-recruiting power. Moreover, the relation between discrepancy and sustained attention is as valid for older children as it is for infants. School-age children will invest longer periods of sustained attentional involvement with events that are discrepant from schema than to those that are congruent with schema (Charlesworth, 1964).

A third determinant of sustained attention, which begins to assume importance during the last part of the first year, involves the richness or density of available cognitive hypotheses for a particular class of events—that is, the degree to which a transformation of a familiar stimulus activates a nest of hypotheses that might explain the event. The richer the network of such hypotheses, the longer the child will remain attentive to the stimulus that elicited these structures.

For heuristic purposes these three conditions can be viewed as additive. Therefore an event that contains high rate of change is a discrepancy from the existing schema of the viewer, if, in addition, the event engages a rich set of hypotheses, it should hold attention with maximal power. The cartoon probably owes its attractiveness to these principles.

Differences in Sustained Attention after Infancy. An important issue in the develop-

ment of attentional processes hinges on the interpretation of the obvious differences in attentional dynamics between preschool and school-age children. The younger child does not typically invest long periods of attention in many activities, and it is often impossible to test him because of his restlessness and distractibility. The 7-year-old, in contrast, is a tractable subject. He persists with tasks, maintains orientation to test objects, and sits for minutes without getting up from the chair. Are these differences between younger and older children due to the young child's inability to focus attention (i.e., his lack of capacity) or due to interference with his existing capacity for attention (e.g., his unwillingness to invest attention in the task)? Earlier theorizing emphasized the younger child's inability, implying that his central nervous system did not permit long periods of focused attention to an activity or to an interesting stimulus. Recent observations of young children suggest that the typical distractibility of a 2-year-old is more likely to be the result of interfering factors than a defect in capacity.

The newborn will show long periods of fixed gazing (Salapatek and Kessen, 1966), and at any month during the first year it is possible to create stimuli that will hold the attention of the infant for several minutes. An attractive, moving, and colorful mobile can elicit prolonged following and fixed attention for 5 minutes or more in a 4-month-old infant. One of us has watched a 1-year-old boy play for 15 minutes with a rubber quoit that bounced and rolled in a unique way each time he threw it. The child would pick up the quoit, throw it, and follow it visually as it oscillated along the floor. The boy repeated this process perhaps 20 times, a laserlike beam of attention binding him to the quoit.

The 2-year-old is capable of sustained attention and inhibition of inappropriate responses on perceptual analysis tasks such as *Embedded Figures*. The child is shown a familiar object (a cat) and a larger stimulus in which the familiar object is disguised or embedded. Most 2-year-olds are able to locate the object after search and are capable of inhibiting false starts and maintaining interest in the problem.

One particular boy is instructive. He was 4 weeks premature (weighed under 5 pounds

at birth), was cyanotic upon delivery, and was in an incubator for the first week. At 4 months, he was immature in his patterns of fixations to faces, motorically retarded, and not alert. At 8 and 13 months of age, he was hyperactive and showed short attention spans. At 27 months of age, he was placed with his mother in a large room and allowed to play for 30 minutes with a set of attractive toys. Most children settle down with a toy, play with it for a minute, and then repeat this pattern with another toy. This boy was pathologically active, and he exhausted himself in very short attentional epochs with the toys. He presented the classic picture of a premature infant with some central nervous system damage. He was hyperactive, restless, and seemed incapable of prolonged attention and inhibition. When he began the Embedded Figures Test, he pointed at the figures randomly and would not sit down to take the test. He ran to the item, pointed haphazardly at the array, and then ran off. He behaved like this for 6 minutes, until his mother suggested that the boy might perform better if he were sitting on her lap. He was put on his mother's lap, she whispered some encouraging words to him, and for 2 minutes and three test items he behaved like a typical 2-year-old. He attended to the array, inhibited false starts, and showed appropriate selective inhibition. Even this child, for whom a diagnosis of central nervous system damage is likely, was capable of sustained attention and inhibition for a time. His capacity for sustained attention was not destroyed. One might argue that the child was not ordinarily motivated to inhibit motoric behavior and attend to external events. There was no goal he desired that would be forthcoming if he inhibited his task-irrelevant motoricity.

A second possibility is that the child had not learned any responses to the toys and task stimuli. Attention is maintained if the external event releases a set of responses. If the child did not know what responses to make to the tasks, his attention would wander. It is not clear which interpretation is correct, but both imply that the lack of sustained attention was not due to any basic incapacity.

The important role of motivation in the apparent capacity for inhibition is seen in the positive correlation among preschool children between the ability to inhibit motor activity

under instruction and quality of intellectual performance, in contrast to the zero-order relation between spontaneous motor activity and IQ (Maccoby, Dowley, Hagen, and Degerman, 1965). The children were asked to draw a line and to walk a line, both as slowly as possible. The children who showed the greatest ability to conform to that instruction had the highest intelligence test scores, despite the relatively restricted range of social class in the sample. Inhibition in the service of a task may be more a reflection of motivation than an inherent defect in inhibitory control.

The motivation to sustain attention on a continuous task is probably one of the most important determinants of quality of performance. Elliott (1964) found that children were much less willing (or able) to sustain attention on an auditory reaction time task than adults. Similarly, Katz and Deutsch (1963) report that grade school boys with reading problems showed much longer reaction times than good readers on trials where the signal to respond was in a modality different from the modality used on the preceding trial (visual to auditory or auditory to visual). Maintenance of a set to respond—which is almost synonymous with sustained attention—may be a central factor in the differential performance of various symptom groups.

The Change in Sustained Attention at Six Years. Developmental scores on selected intellectual tasks show a marked increase in quality between 6 and 7 years of age, in contrast to the less dramatic changes between 5 and 6 years of age. This generalization seems to hold for American children as well as for children in more primitive cultures. S. H. White (1965, 1968) has summarized some of the psychological and biological events that change at this age. They include qualitative differences in transposition learning and reversal shift—nonreversal shift performance, a leveling of the amplitude of the visual evoked potential, which reaches a peak voltage at age six, and a spurt in the growth of neural tissue. The anthropometric literature refers to the growth spurt at age 6 as the juvenile growth spurt. More provocative is Rumlund's comment that between 5½ and 6 much of the symptomatology of the autistic child abates (see S. H. White, 1968). If

the child develops useful language by 6 years of age, prognosis is good, if he does not, the prognosis is poor. In the case of the genetic disorder phenylketonuria, there is some suggestion that the child must take a prescribed diet until about 6 years of age, but he can be taken off the diet after this age with no serious mental retardation resulting. This result suggests that an important reorganization of brain chemistry may occur somewhere between 5 and 7 years of age. Such a conclusion matches the fact that children suffering convulsive seizures during childhood are commonly given medication until about 6 years of age, for this is the time at which febrile convulsions tend to disappear (Carter, 1964).

Consider a recent set of developmental data gathered on 200 children from 4 to 7 years of age living in small villages in Guatemala, none of whom was attending school (R Klein and O Gilbert, personal communication). The children's performance was assessed on the following tests: Embedded Figures Test, Matching Familiar Figures, Haptic Visual Matching Test, Memory for Digits, Memory for Sentences, Incidental Learning, and, finally, Vocabulary. For the first six tests, there was a dramatic increase in performance between 4 and 5 years and 6 and 7 years but minimal change in performance between 5 and 6 years of age. Vocabulary, however, did not show this pattern but rose linearly with age. The tasks that showed this pattern required sustained attention, vocabulary does not require sustained attention. It has been shown that the amplitude of the evoked potential is correlated with the degree to which the organism is attending to the visual stimulus (E Beck and R Dustman, personal communication). There is therefore an association between the amplitude of the visual evoked potential and attentional processes as well as an association between tests requiring sustained attention and a dramatic increase in performance between 6 and 7 years of age. One speculative hypothesis states that the central nervous system changes that may be responsible for the dramatic increase in performance between 6 and 7 are affecting primarily the child's capacity for sustained attention. It is clear that an important experiment in the future would be to devise tasks of equal difficulty graded

for the degree to which they require the child's sustained attention. The tests that require sustained attention should show the 5 to 7 break, those that do not should not.

Attention and Scanning The cognitive control of scanning refers to the distribution of attention. Santostefano and Paley (1964) describe focusers as systematic attention deployers and scanners as unsystematic attention deployers. The initial conceptualization of focusing by Schlesinger (1954) was developed in the context of size estimation. When focusers were presented with disks containing distracting cues for size estimation, they narrowed attention to the critical elements of the task, ignored the distraction, and consequently estimated size more accurately. Subsequent to Schlesinger's work, Piaget, Vinh-Bang, and Matalon (1958) published their evidence on centration effects, that is, the tendency for objects in the center of the attentional field to be overestimated in size as a function of length of focus. Thus the focusing of attention on the standard in a size estimation task should produce less accuracy, whereas extensive deployment of attention should be associated with greater accuracy. With the evidence of Piaget et al (1958) as background, Gardner et al (1959) suggested that the subjects originally called "focusers" by Schlesinger were in reality individuals who scan or deploy attention widely. Accordingly, in subsequent research (e.g., Gardner and Long, 1962a, 1962b), the term "focusing" was dropped and the control principle was designated by the single label of "scanning," referring to the extensiveness of attention deployment. Thus the focusing-scanning dimension as employed by Santostefano and Paley would be designated as extensive versus limited scanning in current usage. Given the greater descriptive accuracy of the latter labels, we shall recast the Santostefano-Paley work accordingly.

Scanning was assessed with a Circles Test in which a standard and a set of variable circles were compared in a context of size estimation. Accuracy of size estimation improved significantly with age. Such evidence is consistent with the view that older children deploy attention more extensively than do younger children and show longer decision times in perceptual tasks. It is not conclusive evidence, however, for no independent measures of the

scanning process were obtained. As Santostefano and Paley point out, data on eye movements would have been exceedingly useful as a check on the actual perceptual behavior of the child.

A useful theoretical discussion of conceptions of broad and narrow attention by Wachtel (1967) has been published recently. That author attributes the confusion in the focusing-scanning domain to the presence of two logically distinct dimensions. Using Hernández-Peón's (1964) metaphor of attention as a beam of light with a central, brilliant focus and a less intense fringe, Wachtel distinguishes between the width of the beam (the original meaning of focusing in Schlesinger's work) and the extent to which the beam moves around the field (Gardner's view of scanning). Wachtel cites the case of obsessive personalities, who "show considerable breadth of attention along the scanning dimension but, metaphorically speaking, tend to view with a narrow and sharply focused beam" (p. 418). In other words, the obsessive individual scans the field for a broad sampling of information but is overly concerned with narrow detail and fails to notice the links between the various elements scanned. Wachtel's discussion brings considerable clarity to a murky area. Any further research dealing with the cognitive controls of focusing and scanning in the realm of attention, whether conducted with adults or children, cannot afford to ignore Wachtel's important conceptual distinction.

Memory

The second cognitive process, following decoding, involves memorial functions. Inquiry into memory processes has been accelerated as a result of the recent, controversial distinction between short- and long-term memory, which has been added to the older distinction between registration and retrieval. It had been assumed traditionally that all decoded events were registered initially with equal strength. If a person could not remember an event that was decoded, the fault lay with the retrieval process, and interference theory was called upon to explain the failure of recall. There was no predilection to reject parsimony and assume different laws for different kinds of storage. Recent data argue in favor of a meaningful distinction between

short- and long-term memory (Adams, 1967). Short-term memory usually refers to a trace available for a maximum of 30 seconds, typically for a shorter period of time. The distinction between short- and long-term memory implies that, without special control processes, decoded information in short-term memory is not transferred to long-term memory and hence cannot be retrieved at a later time.

The problem of diagnosing the content of long-term memory is complex. A description of the traditional methods of studying memory—recognition, recall, and relearning—clearly falls outside the scope of the present chapter. It should be mentioned, however, that the context in which the memory is retrieved is probably central. Although experiments have not elucidated the exact role of context in recalling information, it is reasonable to assume that the context in which the recall is generated affects the completeness of the recall.

Individual Differences Available Units and Memory. Individual-difference dimensions could touch memorial processes in several places. Differences in the availability and use of vocabulary units to encode the event appear to be central factors. After a thorough review of developmental and IQ differences in short-term memory, Belmont and Butterfield (1967) conclude that short-term memory is more influenced by encoding processes than by forgetting.

It is hopefully more than coincidence that John (1967), who approaches the explanation of memorial processes from a neurophysiological point of view, comes to a similar conclusion. John suggests that four different processes might account for differences in the effectiveness of storage of a habit as a result of the action of various drugs. First, a larger number of nerve cells engaged in coherent activity would lead to better storage. Second, the density of coherent nerve cells could remain the same, but the total time that this set of cells was active could vary. Third, the rate of circulation of reverberatory activity could vary, with density of cells and total time constant. Fourth, the contribution of each neural event might be enhanced. John eliminates alternatives two and four because he does not consider them to be viable on the basis of existing empirical data. Thus we are left with either the possibility that the number

of cells involved in storage or the rate at which they operate is the explanation for differences in quality of memory storage. Electrophysiological data presented by John (1967) suggest that the first hypothesis is, at the moment, the most viable. "Learning may be accelerated by involving more cells in the process. More rapid storage is accomplished by increasing the number or density of neurons involved in coherent representation of the event" (p. 63).

This conclusion resembles the suggestion made by Belmont and Butterfield, who surveyed molar recall data. Registration is increased to the degree that mediational units are engaged or elicited by the external stimulus. Differences in effective registration may stem from the density of mediational units, which in turn may be determined by the number of coherent nerve cells evoked by the stimulus.

Lack of existing cognitive units—primarily, but not exclusively, verbal in nature—appears to be one major cause of poor recall. The implication is that the initial registration was also deficient, because registration of information requires units to which the new information can become attached. This suggestion is completely consonant with the observation that children from language-poor environments exhibit performance deficiencies on memory tasks and do not seem to assimilate new information with the fidelity and extensiveness characteristic of children with richer language resources (Cazden, 1966; Hess and Bear, 1968). Similarly, age differences in memory are compatible with variation in the availability and use of verbal mediators (Flavell, Beach, and Chinsky, 1966).

Attention and Memory The dimension of attention provides a second point of contact between individual differences and memory. Lack of selective attention leads to imperfect registration of events, even in short-term memory. Fragility of focus of attention could be the result of several factors, but the two most obvious, and probably the most frequent, are interfering responses and distracting stimuli—preoccupation with other thoughts and visceral afferent sensations (Maccoby and Hagen, 1965).

One of the best validated findings is the negative relation between the quality of immediate recall and anxiety (Kaye, Kirschner,

and Mandler, 1953; Walker and Spence, 1964). Subjects who are made anxious experimentally show poorer recall than those attempting to store material under less anxiety-provoking circumstances. Similarly, children who tried to solve puzzles under ego-involving instructions recalled fewer incomplete, as compared to completed puzzles than they did under task-oriented instructions. Moreover, they recalled fewer puzzles with anxiety-arousing content as compared to those with more neutral content (Smock, 1957). Messer (1968) assessed quality of recall of a simple story under conditions where children had been threatened and under control conditions. He found poorer recall in threatened children.

The favorite interpretation of this relation between anxiety and quality of retention is that anxiety creates distracting stimulation, visceral as well as ideational, which deflects attention from relevant incoming information, and thus impairs memory. The negative correlation between test anxiety and verbal skills is congruent with this idea. An illustration of this notion is contained in Messer's data. The subjects were third-grade boys matched on age and IQ. The following story was read to each subject, with the instruction to recall it as completely as possible.

The American horse known as Man of War was a very fine horse. He ran in races in the United States, in France, and in Germany. He was brown with a red mane and had very strong legs. Five times a year he was in horse shows in Boston where children came to see him trot and run. After watching him the children were served hot chocolate, biscuits, and fudge.

One group of boys was made anxious just before the reading of the story through experimental creation of failure on an anagrams test. The second group did not have this failure experience, and a third group succeeded on the anagrams test. There are two major differences in the recall of the anxious group, in comparison with the others. First, more of the anxious subjects distorted the phrase, "Man of War," and called him either a "war horse" or a "horse that fought in the war." Second, anxious boys were more likely to substitute colors other than brown or red in describing the horse and to substitute foods other

than hot chocolate, biscuits, or fudge. If the anxious children were not completely attentive to the initial reading of the story, the imperfect registration would naturally lead to the kinds of errors described.

Leveling-Sharpening and Memory A third example of individual differences in memory processes is represented by the cognitive control of leveling-sharpening (e.g., Holzman and Gardner, 1960). This control refers to the degree to which the subject holds in memory an image of gradually changing stimuli presented sequentially. Levelers are so named because they merge new stimuli with previously presented ones. Sharpeners, by contrast, maintain a high degree of separation between the memory of previous stimuli and current information. Thus the memorial image of stimuli presented in sequence remains discrete for sharpeners, whereas it tends to lose its articulation for levelers.

The principal measure of leveling-sharpening employed by the Gardner group—the Schematizing Test—requires subjects to make size judgments of a series of squares of progressively increasing size. The test is administered by first presenting the five smallest squares for judgment, once in ascending and then twice in random order. At this point, the smallest square is removed and replaced by a square slightly larger than any seen before. This procedure is repeated after each series of trials, so that all of the squares are eventually replaced. Individuals, of course, vary in the degree to which their judgments reflect or lag behind the actual shifts in size. This individual variation defines the leveling-sharpening dimension in the research of Gardner and his colleagues.

Given the lengthy and tedious nature of the Schematizing Test, Santostefano (1964a) constructed a leveling-sharpening procedure of greater interest value for children. He devised a Wagon Test in which 8 elements of the wagon could be subtracted or added. A Circles Test using a set of 14 circles of gradually increasing diameter was also employed. The child had to note and indicate when a particular stimulus changed relative to the previous exposure. There were 10 boys and 10 girls from each of three age groups—6, 9, and 12—participating in the study.

Three leveling-sharpening scores were derived for each procedure: (1) the point at

which the child detected and reported the first stimulus change, (2) the number of correct changes reported, and (3) a ratio score based on reported relative to actual changes. For all three procedures—Wagon Test (elements subtracted), Wagon Test (elements added), and Circles Test—significant age effects were observed for most of the leveling-sharpening indices. The older children tended toward sharpening, the younger toward leveling. A sex difference in favor of sharpening for boys was obtained, but only in the case of the Wagon Test with elements subtracted. Intercorrelations among the three leveling-sharpening indices were substantial within a single procedure but were low to moderate across procedures. Given the multiplicity of scores, and the variation in the magnitude of the correlations across the two tests, it is not clear whether Santostefano has successfully demonstrated the existence of a generalized leveling-sharpening dimension in children.

Motivation and Memory A final source of individual differences in memory stems from motivational variables. Is the child motivated to work at recalling material, or does he stop searching after the first layer of information has been retrieved? Retrieval is effortful, and the child who works longer is likely to ferret out more information (Hertzog, Birch, Thomas, and Mendez, 1968). The role of motivational factors is considered in more detail later in the chapter.

In sum, variation in quality of recall in children can stem from differences in available mediational units or their use, anxiety, focused attention, susceptibility to distraction, and motivation. One of the perplexing problems is the fact that it is still not clear whether, or to what degree, recall failure is the result of imperfect registration, deficient rehearsal, or the effect of interference on the recall process.

Generation of Hypotheses

Decoding and storage of information are typically the first two processes in a problem-solving sequence. The third process is the generation of possible solution hypotheses—the production of alternative routes of mentation. Individual differences are operative in full force in this phase of the process. Guilford (1956, 1959) refers to this aspect of problem solving as induction. Most standard-

ized tests of mental ability include items that require the generation of mediational links that connect apparently unrelated elements (as in verbal analogies) or the proliferation of characteristics of objects or events. The generation of hypotheses is a fundamental aspect of the problem-solving process.

The number of hypotheses generated is a function of the number and variety of cognitive units in the child's repertoire and the level of permissiveness-restrictiveness in the child's attitude toward error. A third determinant of hypothesis generation concerns the novelty and variety of the hypotheses available. This quality has been the subject of much investigation under the more attractive titles of functional fixedness, rigidity, flexibility, and most recently creativity (see chapter by Wallach in this book).

Generation of hypotheses is so much at the heart of mental functioning that a variety of forces can influence it directly. Anxiety can lead to distraction and interfering hypotheses, motivation affects persistence of search, strength of particular beliefs might prevent proliferation of associations dissonant to the belief. For example, a child who believed that all animals were dangerous might have difficulty recognizing the similarity between mother and cat, even though he possessed the mediational link "alive" in his repertoire.

There are dramatic age differences in hypothesis generation when the task forces the child to rely almost completely on his acquired supply of interpretations and does not give him much information with which to work. Potter (see Bruner et al., 1966) presented to children and adults (age range 3 to 22 years) photographs of familiar objects in a procedure in which the picture was initially out of focus and gradually (in 12 to 14 steps) became clear and obvious. The subject was allowed to view each step for a total of 10 seconds. The younger children, in contrast to the older children and adults, took much longer to recognize the correct picture. The 4- and 5-year-olds, in addition, repeated the same hypotheses frequently and rarely mentioned details in their descriptions of the picture. School-age children, on the other hand, were more analytic in their descriptions and less likely to repeat hypotheses. The older children were also more cautious, often refusing to guess, indicating that they recognized and took ac-

count of the inadequacy of their hypotheses.

Developmental studies of learning set (Levinson and Reese, 1967) document the dramatic differences between preschool and fifth-grade children in the ease with which a discrimination learning set is established. The younger children persist with position hypotheses and specific object preferences, whereas the older subjects have a much stronger faith that there is, indeed, a problem to be solved—not a random walk—and, as a result, are more highly motivated to attend to relevant cues to try to solve the problem.

Hence increased availability of varied hypotheses, greater flexibility in discarding inadequate hypotheses, an appreciation of the formal nature of a problem, and greater anxiety over error are major developmental changes in situations requiring proliferation of hypotheses.

Generation of Hypotheses and Concept-Sorting Tasks. The process of hypothesis generation touches the phenomenon of preferences for particular conceptual groupings. There are developmental and intra-individual differences in the structure and content of conceptual categories produced when the situation is relatively free and allows for a variety of dimensions to be chosen. The bases for regarding a group of objects as alike or as sharing attributes are a function of (1) the stimulus qualities of the objects, (2) the context in which the objects are presented, (3) the child's available categories, and (4) the motivationally based strategies of the conceptualizer.

American research has been overly preoccupied with the content dimensions of form, color, and size (perhaps because of their obviousness), but has neglected equally significant formal categories like symmetry, contrast, movement, or orientation. These latter dimensions are essential, though less static attributes of objects. Unfortunately, too little attention has been paid to categorization of objects or events presented in the auditory, haptic, or olfactory modes.

The child's categorizations can be examined from a formal or content perspective. The formal aspects of a concept or category, which are independent of their specific content, include:

1. **Superordinate (or categorical).** A categorical term is used which characterizes the

common class membership of the objects as wholes (fruits, animals, men, money)

2 **Functional-relational** The bases of similarity involve a thematic relation between or among members of the class (they play together, the match lights the pipe)

3 **Functional-locational** The members of the class share a common location (these animals live on a farm)

4 **Analytic** The basis for categorization involves similarity in a *manifest* component of the members of the class (these have two arms, these have feathers)

Recent work has revealed lawful developmental trends in the use of these four modes (see Sigel, 1953, 1964). With age, the child is more likely to use superordinate categories and less likely to use functional-relational categories. Children 4 to 6 years of age usually classify visually presented objects or pictures into functional-relational categories (the boy and the dog play together, the paper and the match burn). Older children prefer superordinate and analytic groupings (Kagan, Rosman, Day, Albert, and Phillips, 1964). Among young children, those of lower social-class background are apt to give more functional groupings than middle-class subjects of the same age (see Sigel, Anderson, and Shapiro, 1966).

The Significance of Analytic Concepts A series of studies has suggested that the production of analytic concepts with visually presented material increases with age (Kagan et al., 1964) and seems to be in the joint service of a reflective attitude and a preference for visual analysis. Trios of pictures were shown to children from 6 to 11 years of age. The child had to select two pictures that were "alike in some way." The pictures were constructed so that analytic, functional-relational, or superordinate groupings were possible. There was a linear increase in number of analytic concepts with age for children in grades one to six. Moreover, the children who produced many analytic concepts obtained higher scores on the Picture Arrangement subtest of the Wechsler Intelligence Scale for Children but were not superior to other children on the Information or Vocabulary subtests.

In one experiment, children were either told to pause and delay before giving their

conceptual grouping or urged to respond quickly. The first instruction produced increased analytic responses. This finding was replicated for nonanalytic children, but analytic children did not produce fewer analytic responses when told to respond quickly (Ostfeld and Neimark, 1967). More impressive is the fact that within a group given the same instructional set (to respond quickly or slowly), there was a positive relation between response time to produce a concept and number of analytic concepts. The children with many analytic concepts made fewer errors in match-to-sample tasks and showed longer decision times on these tasks.

The production of analytic concepts to pictorial stimuli with subtle analytic detail seems to be mediated by tendencies to reflect over the validity of the response and to engage in analysis of visual arrays (Lee, Kagan, and Rabson, 1963). Children were taught to associate a nonsense syllable with a series of geometric designs that had figure and ground components. After reaching criterion the child was shown the figure and ground components separately. Fourth-grade boys who produced many analytic concepts were more likely to label the figural component correctly when it was presented alone.

In a similar study, third-grade boys were classified as showing a high versus low disposition to produce analytic concepts on a task in which the child had to group pairs of stimuli from sets of three pictures. These children were then administered a concept-induction task where the child had to induce the concept for visual stimuli that contained two analytic, two relational, and two categorical concepts. Nonsense syllables were used to represent the conceptual categories. The analytic children attained the analytic concepts before the relational or categorical concepts. The relational boys, on the other hand, showed the opposite pattern. Thus when familiar materials are used, an analytic attitude shows some generality (Lee et al., 1963).

Consider now some other characteristics associated with a preference for an analytic mode of categorization. Observation of normal children who were both analytic and reflective, in contrast to those who were non-analytic as well as impulsive, indicated that the first group was more attentive and less distractible in a normal classroom setting.

(Kagan et al, 1964) School-age children who produced analytic concepts were likely to have spent long periods of time in solitary task activities during the first four years of their lives (Kagan et al, 1964) This evidence is concordant with the report that kindergarten boys who produce analytic groupings are rated as more controlled emotionally than boys who produce categorical or relational concepts (Sigel, Jarman, and Hanesian, 1967) In sum, school-age children who produce analytic concepts with familiar, visual material seem to be more reflective, less distractible, and more likely to analyze pictorial arrays

The Meaning of the Child's Conceptual Response It is important to note that the data quantified are typically the child's verbal explanations of his conceptual groupings It is possible that the child was thinking in superordinate terms, but because he did not have the words for a superordinate explanation, he employed a functional basis for categorization Moreover, the child might have realized that he would have to explain his grouping and, as a result, selected a grouping that he was capable of explaining, rather than one he would have used had he not been under the social pressure to account for his behavior This is a serious methodological problem that reminds us of the competence-performance distinction in psycholinguistics Much of our data on preferred conceptual categories may be specific to the artificial laboratory situation in which it is gathered

A second, controversial issue concerns the relation between developmental trends and the specific nature of the array categorized by the child Some investigators have suggested that age trends are independent of the specific material being sorted However, the data question the validity of this view Lower-class Negro children have much more difficulty categorizing pictorial representations of familiar objects than three-dimensional representations of these objects (Sigel et al, 1966, Sigel and McBane, 1967, Sigel and Olmsted, 1967)

Olver and Hornsby (in Bruner et al, 1966) asked subjects 6 to 19 years of age to state the similarity among groups of words The child was first read a pair of words, a third word was added to the pair, a fourth was added to the trio, and so on, until eight words had been presented for successive similarity

judgments The use of analytic bases to tie the words together decreased with age, while superordinate categories increased Another group of subjects (6 to 12 years of age) was presented an array of 42 pictures of familiar objects and asked to select those that were "the same in some way" Analytic concepts were more frequently used with the pictures than they were with the words However, analytic concepts decreased and functional concepts increased with age Kagan et al (1964), on the other hand, who also used pictures of objects as instances to be grouped, found that analytic concepts increased while functional categories decreased with age

The fact that the use of a preferred mode of categorization depends on the specific test materials presented to the subject is further illustrated in a study by Gilmore (1968) Ten-year-old children were asked to name some familiar adults and to state how these adults were similar These children also sorted pictures of people into conceptual categories Reflective girls (girls who showed long response times on tests of uncertainty) produced many analytic concepts when stating the similarity among the five familiar adults (a verbal task), but showed no preferential tendency to produce analytic concepts to the picture-sorting task Similarly, middle-class, elementary school children produced many more analytic and relational concepts when they were sorting human figures than when they were sorting objects or animals However, older children produced more analytic responses for all classes of stimuli—people, objects, or animals (Sigel and Olmsted, 1967) Still another investigation (Wallach and Kogan, 1965) found that creative children give more functional concepts than less creative, but equally intelligent children

On the surface there seems to be little consistency in these diverse sets of data Some order emerges if one takes into account the nature of the array being sorted By nature of array we mean the modality in which the information is presented as well as the relative salience versus subtlety of the bases for grouping Let us consider some assumptions about sorting behavior before proceeding further

A 3-year-old child has already developed standards concerning quality of concepts and quality of performance He has begun to learn

what are, in his culture, the characteristics of good or appropriate concepts, and, indeed, even the characteristics of esthetically pleasing concepts. Part of his judgment is related to the subtlety of the category as reflected in the amount of work required to detect it. The extraction of pleasure from an event, as evidenced by the nonsocial smile, is likely to occur when the person attains a successful solution following a period of mental effort. The smile is not likely to occur if minimal effort was associated with goal attainment. This generalization is illustrated in several contexts. If one observes a parent watching his child being tested, the parent is most likely to smile when the child succeeds either following a failure experience or after a difficult item where the parent has had a chance to build up some uncertainty about the outcome. If the child succeeds on an easy item, the parent is not likely to smile. The child also is most likely to smile when he succeeds on a test item that follows a long period of search. He is unlikely to smile following success on an item requiring no work. These observations suggest that the child has acquired an association between success on a difficult task, on the one hand, and positive affect, on the other. A child of 5 years seems "to know"—in the sense that he can tell you—which concepts are "good" and which are "bad" on purely formal grounds. The defining criteria depend, in part, on difficulty of detection. An answer to a hard problem is more valuable than an answer to an easy one (see Smith and Wing, 1961). The nature of the array is an important determinant of the concepts chosen by the child. If the array makes functional concepts easy to detect and analytic ones difficult, the older child is more likely than the younger to select the analytic concepts, because he believes them to be better or more elegant. The older child may choose the analytic concept not because he failed to note the relational, but because he preferred the analytic. If the analytic concept were obvious and the relational one subtle, he might do the opposite. Thus Kagan et al. (1964), using pictures that made functional concepts easy to detect, found a decrease in their use over age. On the other hand, using an array for which functional concepts were difficult, Olver and Hornsby (1966) found an increase in their use over age.

As suggested earlier, the mode of presentation is also critical. In the Olver-Hornsby work, where words rather than pictures of objects were used, the functional bases were relatively easy to produce. Analytic concepts are unlikely with older children when words are the events categorized. The child is not likely to produce an analytic conceptual basis to the two words potato and banana, but he might say "both have spots" if he saw them illustrated. There are major interactions between the child's stage of development and the relation between the specific nature of the array and the conceptual categories reported by the child. The power of these interactions should increase with age, for the older child has greater freedom of category selection.

Perhaps the best illustration of the importance of the array on the nature of the dimension selected is contained in Wohlwill's (1963) study of relational versus absolute response to number. Children in grades 1, 3, 5, and 8 were rewarded either for an absolute choice of number 5 (when the number 1, 2, 3, 7, 8, or 9 was paired with the number 5), or they were rewarded for a relational choice, where the child had to pick the smaller number of the pair. One group of subjects was exposed to a perceptual representation of the numbers (e.g., 5 dots versus 7 dots). Other children were exposed to an abstract representation (5 triangles versus 7 crosses). Still others were exposed to pairs of numerals (the numeral 5 versus the numeral 7). Under the perceptual and abstract modes of presentation, the relational discrimination was much easier than the absolute. Under the numeral condition, the absolute choice was much easier. The importance of mode of presentation was clearest among the first-grade children. Under the perceptual condition, learning the relational response was easy, under the numeral condition, the absolute response was easy to attain, under the abstract condition, neither the relational nor the absolute response was easily learned. It is not reasonable to conclude that first-grade subjects are preferentially relational in their thinking about number, or preferentially absolutistic. Their preferences depend intimately on the specific nature of the material being presented. A preferred conceptual response is rarely independent of the materials to be classified (Wohlwill, 1963).

There is a more profound moral contained

in these data and implied by this general discussion. The child learns classification responses to specific sets of events. He classifies events and does not always carry around a generalized conceptual rule for all stimulus contexts. This principle holds as well for Kendler's and Piaget's empirical generalizations as it does for those based on object sorting data. Children of 3 years of age will not show mediational reversal shifts involving the size and color of squares in a typical Kendler laboratory procedure (Kendler and Kendler, 1962). But absence of a reversal shift in this context is not a sufficient data base to declare that a 3-year-old does not mediate when he arranges six sticks in a vertical position, blows at them, and sings "Happy Birthday." A 5-year-old may not classify on two dimensions simultaneously if he is presented with pictures of birds and leaves in a Geneva, Denver, or Cambridge laboratory. But that observation is not sufficient to conclude that 5-year-olds never classify an event on two dimensions simultaneously. Younger children do this each day when they load all the red, square blocks in a wagon and leave the red and blue circular ones.

Psychology is concerned, naturally with generalized laws about responses and cognitive functions. Our theoretical ambitions tempt us to proclaim that cognitive structures displayed in one limited situation can be generalized across varied situations. It would be convenient if children possessed generalized rules rather than specific reactions to specific classes of events. However, much of our data fail to support this wish. Save for a few exceptions (e.g., the syntactic behavior of the young child), there is less transfer than we like to believe. This issue is reminiscent of the old transfer of training controversy in educational psychology. Existing empirical research suggests that a child learns a set of skills to a particular class of problem. Generalization of preferred conceptual categories is limited. Statements about individual differences in categorization strategy must contain a strong statement about the materials manipulated. A child may be analytic with visual stimuli containing subtle analytic cues but superordinate with verbal representations of those objects. The descriptive term "analytic" is not different from the word "prejudiced." In both cases we must know the target of the attitude.

The Role of Evaluation in Problem Solving

Let us focus now on a fourth process in problem solving. The degree to which the child pauses to *evaluate* the quality of his cognitive product acts on the entire spectrum of cognitive processes by influencing the quality of initial decoding, recall, and hypothesis generation. Some children accept and report the first hypothesis that is printed on the screen of awareness and act upon it with only the barest consideration for its appropriateness or validity. Others devote a long period of time to study and reflection and censor many hypotheses. This individual-difference dimension is apparent in children as early as 2 years of age.

The hardness of this evaluative dimension is beautifully illustrated in a psychophysical study of light intensity. Ten trained adult subjects judged whether a light was on or off in a situation in which light intensities were close to threshold. The adults viewed the lights under three viewing conditions—both eyes, dominant eye, and nondominant eye. Decision time was the variable quantified. Although response times decreased with increasing light intensity and were fastest with use of the dominant eye, as might be expected, there was a subject-by-intensity and a subject-by-viewing condition interaction which was significant at less than .01. Even under these stringent, experimental conditions with trained observers, consistent individual differences in decision time emerged. Some adults make decisions quickly, others slowly (Minucci and Connors, 1964).

The evaluation dimension is relevant to all ages and can be assessed with a variety of instruments. Our discussion focuses on one series of related investigations with children that used the same instruments to index this dimension, called reflection-impulsivity.

The reflection-impulsivity dimension is concerned with the degree to which the subject reflects on the validity of his solution hypotheses in problems that contain response uncertainty. There are many test procedures that would be adequate indexes of this disposition. The specific test used most often is called Matching Familiar Figures. The child is asked to select one stimulus, from six variants, that is identical with the standard. Number of errors and response time to the first hypothesis are the two major variables coded. There

is a clear and dramatic decrease in errors and a corresponding increase in response time with age, over the age range 5 to 11 years, in American children. Moreover, at every age there is a negative relation between response time and errors—usually ranging between -40 and -65 (Kagan, 1965a, 1965b, 1965c, 1966).

Reliability of Reflection-Impulsivity The short-term stability of this dimension is illustrated in a study with second-grade children tested for 10 weeks in a row on variations of Matching Familiar Figures in which the number of variants was increased by one each week (Yando, 1968). The first week the child was shown a standard and two variants, the second week a standard and three variants, the third week a standard and four variants, and so on through ten tests, in the last of which the child was shown the standard and twelve variants. Looking at the response-time and error scores for children previously classified as reflective, impulsive, or neither, one finds a remarkable stability of the tendency to be reflective or impulsive. The average correlation for response time across the 10 weeks was $.70$. There is also good long-term continuity for the reflection-impulsivity classification. In one study, 104 boys and girls were individually administered one version of the MFF when they were in grades three or four and a different version one year later. The correlations between response time on the first and second administrations were high for both sexes and averaged $.62$. A second study of stability involved a group of 102 children who were given the Matching Familiar Figures Test in the spring of their first year in school and one year later were administered the same test again. The stability correlations for response time were $.48$ for boys and $.52$ for girls (Messer, 1968). The stability of response time over a period of $2\frac{1}{2}$ years was $.31$. In general, the tendency to display fast or slow decision times to this response-uncertainty problem is relatively stable among young children over a short period of time and, as we shall see, generalizes to other tasks.

Generality of Reflection-Impulsivity across Tasks Evidence for the consistency of this disposition can be seen in the cross-task generality of the tendency to be impulsive or reflective. The correlations between response time on the Matching Familiar Figures task and re-

sponse time on a Haptic-Visual Matching task were consistently high across many samples of children in the first three grades (Kagan, 1965c, Kagan et al., 1964). Correlations for response time on each task ranged from $.61$ to $.87$, with a median coefficient of $.64$. Comparable correlations were found in kindergarten children for two variants of the matching figures task (Ward, 1968b). It is important to note that there is generally a low, usually nonsignificant relation between language skills and this dimension. The correlation between response time and the verbal scale of the Wechsler Intelligence Scale for Children is usually under $.20$, but it is higher for girls than for boys. The tendency to show long versus short decision times in selection of a hypothesis also generalizes to tasks in which the child must generate his own alternative hypotheses. Inkline drawings of incongruous scenes were presented tachistoscopically to a group of young children in the second and third grades (Kagan, 1965a). The pictures were shown at increasing exposures for a minimum of 18 trials. Each child made a minimum of 108 descriptions across all 6 scenes, and the response latency from exposure of picture to first significant verbalization was recorded. The response time on the tachistoscopic recognition task was positively related to the response time on MFF ($r = .40$, $p < .01$ for 60 boys, $r = .40$, $p < .01$ for 53 girls).

Reflective and impulsive children behave differently in an interview in which they are answering an adult's questions. A group of 56 boys and 52 girls in the fourth and fifth grades were individually interviewed by a female adult about their hobbies, subjects in school, and favorite pastimes. A sample question would be, "What games do you like best to play?" or "What are you poorest at in school?" Most of the questions had some degree of uncertainty. The interview was tape recorded, and the tapes were scored for temporal delay between termination of the interviewer's question and the beginning of the child's reply for a series of 20 questions. The average delay score across the 20 questions was computed for each child, and this score correlated with measures of reflection-impulsivity gathered earlier. Correlations with response time on MFF were $.30$ for boys and $.38$ for girls ($p < .05$). In sum, there is some generalized tendency for a child to show long or

short decision times across various kinds of problem situations that contain response uncertainty

Reflection-Impulsivity and Recall Impulsive children are likely to make errors of commission in a serial-recall task, which reflective children rarely do. In one study, over 200 third-grade children were assessed for their tendency to be reflective or impulsive using the Matching Familiar Figures task. Three months after this session, the children were seen for a serial-learning task in which lists containing 12 familiar words were read, and each child was asked to recall the words on the lists. Each subject was given two trials on each list, the second trial presented the words in an order that was an exact reverse of the first trial. After the first two lists, during which all subjects were treated alike, three different experimental treatments were created. One group, the threat group, was told that the first two lists did not count, and they would have to do very well on the next two lists, which were very difficult. The intent of this communication was to arouse anxiety over possible failure. The children in an adult rejection group were told that their performance was poor, and they would have to do better. The control group was told nothing. Two new lists were read to the children. Children in both anxiety conditions produced more errors of commission than those in the control condition. The impulsive children made many more errors of commission on both prethreat and post-threat lists. The reflective children who were made anxious over possible failure showed a larger increase in errors of commission than reflective children in the control group who showed the smallest increase in errors of commission. Thus anxiety as well as a disposition toward impulsivity lead to substitution of incorrect for correct elements in recall tasks (Kagan, 1966).

Decreases in an impulsive style of responding have been obtained by means of experimental instructions deliberately discouraging guessing under conditions of uncertainty. Gould and Stephenson (1967) read Bartlett's passage, "The War of the Ghosts," (Bartlett, 1932) to 75 adults and obtained recall under three different instructional sets. One group was instructed to "write down the story I've just read to you as exactly as you can." A

second group was told to write down "as much as you can remember. Don't set down facts and incidents which were not in the original. Do not invent material to fill the gaps for the sake of being able to tell a complete story, leave blanks." A third group was told to write the story "as best as you can. Take care that each item you set down corresponds with something in the story, not word for word, but fact for fact. If you come to something you can't remember, don't fill in to make a story of it, leave a blank. If you have doubt over an item, come down on the side of doubt, don't come down on the side of certainty." Later, each subject was read his own reproduction and was asked to indicate how certain he was of the elements he reproduced. Group one, which was not given any specific warning about inhibiting guesses, produced recalls with the greatest amount of error; there was no difference in error rate between groups two and three. Instructions to inhibit guesses reduced error rate dramatically.

Reflection-Impulsivity and Reading Prose Reflective children make fewer errors in reading English prose than impulsive children (Kagan, 1965b). First-grade subjects (65 females and 65 males) were assigned to reflective or impulsive groups based on their performance on the Matching Familiar Figures task. They were then shown a card on which five words were printed. The examiner read one word aloud and asked the child to point to the single word on his card that matched the one that had been read. The longer the child delayed before offering a solution hypothesis on the Matching Familiar Figures task, the more accurate his initial recognition of the words spoken by the examiner. Although verbal ability predicted quality of performance, the relation between a reflective orientation and reading errors remained significant even after the influence of verbal skills had been partialled out ($r = .28$ for boys, $r = .28$ for girls, $p < .05$). The multiple correlation, using word errors as the criterion and verbal skills and response time as separate predictors, was .51 for boys and .59 for girls. When the correlations were computed separately for children high or low on verbal ability, the results were more dramatic for the high-verbal children. Among high-verbal children the correlations between response time on MFF and reading-word errors were $-.21$ for boys and

— 44 for girls, while the corresponding correlations for low-verbal children were — 14 for boys and — 21 for girls. The low-verbal children had acquired minimal reading skills, and therefore their delays and errors were less a function of response uncertainty than they were of conceptual deficit. This situation is analogous to asking the authors to write the equation describing the trajectory of Mariner IV. The ensuing delay reflects incompetence, not cautious brooding over a set of alternative answers. When these same children were seen one year later, in the spring of their second year of school, they were asked to read some prose paragraphs. The impulsive children made more errors than the reflective. The most frequent error was one in which the child articulated a word that had some graphemic similarity to the correct word—for example, reading nose for noise or truck for trunk (Kagan, 1965b).

Reflection-Impulsivity and Reasoning The reflection-impulsivity dimension also influences quality of inductive reasoning. First-grade children previously classified as reflective or impulsive were given tests of inductive reasoning. For example, on one test the child was given three attributes of an object, and he had to guess the object (e.g., What is yellow, melts in the sun, and you eat it? What has doors, wheels, and moves?). In a second procedure, the child was shown three pictures in a fixed order that portrayed the beginning of a story sequence. He was then given four more pictures and asked to select the one picture (from the four) that illustrated the next thing to happen in the story. On both procedures the impulsive children responded more quickly and made more errors than the reflective children (Kagan, Pearson, and Welch, 1966a).

Reflection-Impulsivity and Tracking Patterns Recent studies of the eye tracking patterns of reflective and impulsive children are consonant with the suggested interpretation of their molar behavior (Drake, 1967). Third-grade children, previously classified as reflective or impulsive under ordinary test conditions, took the Matching Familiar Figures Test while seated at a Mackworth eye camera so that their eye fixation patterns could be recorded on film. During the first 6 seconds of each test item, the reflective children made more homologous comparisons than the im-

pulsive. A homologous comparison is a visual comparison of similar details across the variants (i.e., the dog's tail in variant 1 is compared with the tail in variant 2). If one examines the data during the time prior to the first response (which is longer for reflectives than for impulsives), reflective children covered more details in the pictures and scanned more variants. In effect, the reflective children made a more careful visual search of the standard and all four variants before they were willing to offer a response to the examiner. This molecular scanning behavior is congruent with their response-time and error scores (Drake, 1967).

In similar studies, fourth-grade boys were administered the Matching Familiar Figures Test in the following way. The standard and six variants were placed behind frosted glass compartments. For the child to view the stimuli, he had to press a manipulandum. Quantification of these instrumental responses permitted a rough reconstruction of his probable tracking behavior. The reflective child had longer average durations of looking for each visual opportunity, especially when looking at the variants. More important, however, the reflective children tended to examine all of the variants, whereas the impulsive boys looked at only one or two of them and then offered a solution hypothesis. The reflectives were cautious, the impulsive children adopted a much riskier strategy (Nelson, 1968; Sigelman, 1966).

In general, lower-class Negro children are more impulsive than middle-class Negro children, and lower-class Negro mothers are more impulsive than middle-class Negro mothers (Hess and Shipman, 1965). Several studies have shown a nonsignificant but suggestive trend toward greater impulsiveness for children who are low in intelligence but high on performance on the Wallach and Kogan (1965) creativity test procedures (Ward, 1966, 1968a).

Modification of Reflection-Impulsivity Several studies indicate that the disposition to be reflective or impulsive can be modified. First-grade children were divided into training and control groups. The training consisted of requiring the children to inhibit a response for 15 seconds. After a few 30-minute training sessions, trained children exhibited longer response times to a strange examiner who did

not impose any time constraints. However, error scores were not influenced to any appreciable degree by the training (Kagan, Pearson, and Welch, 1966b).

A training regimen that emphasizes accuracy only and ignores speed of response produces both longer response times and fewer errors in impulsive children (Nelson, 1968). Fourth-grade boys previously classified as reflective or impulsive on the MFF were trained to be more accurate in their selection of the correct variants, using geometric forms rather than pictures of familiar objects. Control subjects were exposed to the training apparatus and stimuli but experienced no training. After training, the impulsive boys showed marked increases in response time and marked decreases in errors, when contrasted with the untrained controls. The trained reflectives showed the same effects, but the differences were not as large.

In another extensive training study, fourth-grade children previously classified as reflective or impulsive were placed into one of three groups: trained to be reflective, trained to be impulsive, or trained to be neither. Reflective subjects trained to be reflective became slower than those trained to be impulsive, whereas impulsive children trained to be impulsive became faster. Each type of child was capable of modifying his preferred speed of responding. Moreover, error scores were affected in the expected direction (Briggs, 1966).

Debus (1968) attempted to modify response time through modeling procedures. A group of 100 third-grade children were assigned to one of four experimental modeling groups or a control group. The model was a sixth-grade child the same sex as the subject. The subject saw the model perform on 10 items of the Matching Familiar Figures Test. One group watched an impulsive model who showed latencies of 7 seconds. The second group watched a reflective model who showed latencies of 30 seconds. A third group watched a model behave impulsively for five items and then behave reflectively for the last five items. A fourth group was exposed to two models—one reflective and one impulsive. The fifth group, a control, watched no model at all.

The subjects were tested immediately following exposure to the model and tested again 2½ weeks later. The largest increase in

response time on the immediate test occurred for children who had watched the reflective model (an increase of about 12 seconds). On the delayed test, 2½ weeks later, the boys who had watched a reflective model showed longer response times than all other groups. Among girls, exposure to any reflective model (group 2, 3, or 4) led to increased response times on the delayed test, whereas the controls and the subjects exposed to the impulsive model were markedly faster. Exposure to a reflective model led to slower response times for all subjects, with girls being more influenced than boys by any exposure to a reflective performance. As in earlier studies, errors were not changed, despite the increase in response time (Debus, 1968).

A similar finding in a more naturalistic setting has implications for the educational establishment. Each of 20 first-grade teachers was classified as reflective or impulsive using an adult version of the Matching Familiar Figures Test. A random sample of subjects from each of the 20 classrooms was tested in the early fall and then again in the late spring to determine if exposure to a teacher with a preferred strategy influenced the child's tempo. The children changed in a direction consonant with the teacher's tempo, the effect being most marked for impulsive boys assigned to a classroom with experienced reflective teachers. These boys showed the greatest increase in response time from fall to spring (Yando and Kagan, 1968).

The Dynamics of Reflection-Impulsivity
The tendency to be reflective or impulsive is stable over both time and tasks and is somewhat modifiable. How can we conceptualize the psychological bases for this disposition? As with most behaviors, it is likely that a reflective or impulsive attitude can be in the service of several different forces.

One dynamic could be based on the assumption that a strong motive to appear competent may prompt too rapid a conclusion. Since our culture generally equates speed of thinking with intelligence, a person who required validation of his intellectual competence would be predisposed to produce answers quickly. This tendency should be strongest in those who had some doubt of their ability and, in addition, were anxious over this deviation from a standard. Thus a child who doubted his ability, but wished to deny

this doubt, would behave impulsively. A child with a strong fear of failure, and no strong tendency to disguise it, is likely to become reflective. A child with minimal anxiety from either source would be neither extremely reflective nor extremely impulsive. An impulsive or reflective strategy can be the result of anxiety, but the source of anxiety is different in the two types of child. For the reflective, the source of anxiety derives from the expectation that the social environment will regard the person as incompetent because he has made a mistake. For the impulsive, the source of anxiety derives from the expectation that he will be judged incompetent if he responds too slowly. The difference hangs on the behaviors that will be judged negatively.

It is possible that this difference in personal definition of competence and the subsequent differences in strategy have historical links during the preschool years. The child who experienced continual emphasis on avoidance of error (i.e., he was praised for inhibiting asocial behavior) would define adult approval and positive self-evaluation in terms of *inhibition of inappropriate behavior*. The child whose experience emphasized success (i.e., praise for successful walking, climbing, and talking) might define adult approval and competence in terms of success at difficult tasks, that is, in terms of active accomplishment rather than inhibition of the inappropriate. The child who experienced reward for success may set up an unrealistic standard for level of competence required for approval and be pushed constantly to action, often impulsive in nature, in order to attenuate the anxiety over the thought, "I may not be competent."

A simpler dynamic, to which we feel more friendly and for which the evidence is much better, suggests that the greater the fear of making a mistake, the more reflective and cautious the performance. Minimal anxiety over a potentially inaccurate answer is likely to be a primary determinant of an impulsive performance. Reflectives seem to be overly concerned with making a mistake and wish to avoid error at all costs. Impulsives seem minimally apprehensive about error and consequently respond quickly. It will be recalled that impulsive subjects did not scan all the alternatives before offering a solution hypothesis and reported words that they did not hear in a serial recall procedure.

A recent study lends the strongest support to this notion. Third-grade boys initially categorized as reflective or impulsive on the basis of their time and error scores on the Matching Familiar Figures Test were assigned to one of three experimental groups. Those in a "failure" induction group were administered a difficult anagrams test and led to believe they had performed poorly. A "success" group was administered the same anagrams test but was led to believe those in the group had performed well. A control group experienced neither success nor failure. Immediately after the manipulation, each child was administered a new version of the Matching Familiar Figures Test and changes in response time and errors were recorded for each group.

The impulsive and the reflective boys in the success group showed a decreased response time on the posttest, the failure and the control groups showed an increased response time. An independent study revealed that the control group interpreted the second administration of the Matching Familiar Figures Test as indicating that they must have performed poorly on the first administration. Thus the children who were likely to be most anxious over the quality of their intellectual performance showed the largest increases in response time. Moreover, the subjects who showed an increased response time also displayed a decrease in errors on the posttest, the children who did not display an increase in response time made more errors on the posttest (Messer, 1968).

A cross-cultural study of developmental changes in decision times to the Matching Familiar Figures Test furnishes important indirect support for the relevance of anxiety over error. Mayan Indian children (5, 6, and 7 years of age) living in small villages in Guatemala were administered a culturally appropriate version of the Matching Familiar Figures Test along with a battery of other tests (R. Klem and O. Gilbert, personal communication). Although quality of immediate memory, Embedded Figures Test performance, and vocabulary scores all increased with age, there were no significant changes in response time or error scores on the Matching Familiar Figures Test across the age period of 5, 6, and 7 years. Moreover, the mean response times were well under 5 seconds. Comparable data gathered on American children

during this age period indicate dramatic increases in response time with age and corresponding decreases in errors. Close observation of these Guatemalan children during testing suggested that they persisted in coping with the task, but they showed minimal signs of disturbance or anxiety in the face of failure. American children tend to become resistant and restless when they fail one or two items on any test and often withdraw from the task after several failures. The Indian children showed neither signs of task withdrawal nor any evidence of distress when they failed. Their relatively fast decision times were accompanied by evidence of little anxiety over error. This minimal anxiety may in fact account for the fast performance in the sample studied.

Similar conclusions can be drawn from a study by Weintraub comparing normal, hyperaggressive, and overly inhibited 11-year-old boys from middle- and lower-class backgrounds (S. Weintraub, personal communication). The effect of type of pathology was more important than social class. The boys with externally directed symptoms (aggression, lying, cheating, delinquency) were dramatically more impulsive on the Matching Familiar Figures Test than the children who showed internalized symptoms (fears, phobias, signs of guilt). The preferred interpretation of the difference between an internalizing or an externalizing symptomatology hinges on the excessive fear and anxiety over adult disapproval characteristic of the internalizing children, contrasted with the minimal fear of violating social norms characteristic of the externalizing children. The fact that the externalizing boys were more impulsive than their internalizing counterparts is persuasive support for our interpretation of the reflection-impulsivity dimension.

Moreover, the developmental increase in a reflective strategy among American children is accompanied by a change in the more general disposition to grow more cautious with age, i.e., to become increasingly concerned with avoiding a mistake. Draguns and Murtari (1961) showed children in grades 1, 3, 5, and 7 an ambiguous picture and then gradually added clues which decreased the ambiguity of the stimulus. The younger children offered guesses early, whereas the older children were cautious and inhibited hypotheses

until they were more certain of the accuracy of their response. Similar results are reported by Mosher and Hainsby and by Potter (in Bruner et al., 1966) as well as by Westcott (1968).

Is the age-related increase in caution, as reflected in avoiding mistakes and inhibiting hypotheses, also found in risk-taking behavior conceived more generally? Kass (1964) obtained no age differences between 6-, 8-, and 10-year-olds in a "pay to play" gambling situation. Cohen (1960), on the other hand, reported very substantial differences in risk taking between 9-, 12-, and 15-year-olds in a gambling context with candy as the incentive. The decline in risk taking with age in Cohen's work may, however, simply reflect the lesser incentive value of candy for the older children. Sex differences in risk taking (under gambling conditions), in favor of boys, have been observed by Kass (1964) in the 6 to 10 age range and by Slovic (1966) in the 11 to 16 age range. A comprehensive review of age and sex differences in risk taking is available in Kogan and Wallach (1967).

It should be emphasized that test anxiety as conceptualized and measured by Sarason, Davidson, Lighthall, Waite, and Ruebush (1960) is not synonymous with what we have called anxiety over error. Typically, scores on test anxiety questionnaires are not correlated with long decision times or errors in tasks with response uncertainty and do not predict the phenomena that are correlated with a reflective attitude (see Messer, 1968; Palermo, 1961; Phillips, King, and McGuire, 1959).

Review of the literature (Ruebush, 1963) relating test anxiety to intellectual performance suggests consistently negative ($r = -.20$ to $-.30$) correlations between scores on test anxiety questionnaires and verbal IQ tests or tests of verbal ability. The correlation between test anxiety and either intelligence or achievement test performance is fairly low in the primary grades, increasing with grade level (Hill and Sarason, 1966; Sarason, Hill, and Zimbardo, 1964). Typically, there is no consistently reliable relation between test anxiety and scores on tests that minimize the verbal component of performance. Stevenson and Odom (1965) correlated test anxiety scores with children's performance on a variety of learning and problem-solving tasks. There was no relation between test anxiety

and ease of discrimination learning, but a negative correlation between test anxiety and performance on such verbal tasks as paired associates and anagrams. The index of reflection-impulsivity does not involve verbal processes, and perhaps that is the reason for the minimal relation between test anxiety scores and the reflection-impulsivity dimension.⁸

Consider, finally, the matter of sex differences and attitude toward error. Sex differences in level of performance on varied intellectual tasks are less common than sex differences in the pattern of relations among performances. Lewis, Rausch, Goldberg, and Dodd (1968), for example, found no sex differences in mean response time or error scores on a test of reflection-impulsivity, but they found errors to be more strongly related to IQ in girls than in boys, and more strongly related to response times in boys than in girls. Maccoby (1966) has prepared a most valuable summary of the literature on sex differences. She proposes an integrative hypothesis in which a personality dimension of inhibition-impulsiveness is presumed to be curvilinearly related to quality of intellectual performance. Boys and girls occupy different positions on this dimension as indicated in Fig 1 (from Maccoby, 1966). Extremely inhibited girls and extremely impulsive boys give the poorest performance. Girls must become less inhibited and boys more inhibited in order to

⁸ Kimble and Posnick's (1967) demonstration of a high positive correlation between the test anxiety score and a score on a comparable scale in which all semantic references to anxiety were deleted highlights the enigma of the anxiety construct.

Fig 1 Relative positions of girls and boys on a hypothesized personality dimension, running from inhibited to impulsive, which is curvilinearly related to quality of intellectual performance

increase the quality of their performance on most intellectual tests. Existing research generally supports this hypothesis, for one finds that boys are usually more willing to tolerate the risk of error than girls (see Wallach and Caron, 1959). Maccoby's hypothesis implies that when sex differences occur for particular intellectual performances, they may be the result of differences in attitude toward error, rather than differences in decoding, memory capacity, or hypothesis generation. Sex differences in these latter functions, when observed, may in fact be linked to a "cautiousness" vector.

The Role of Evaluation in Decision-Making Tasks. Many experimental tasks and procedures involve evaluation in the sense described previously, although this may not be apparent from the title of the construct cited in the published report (see fn 5). Age differences in performance on these procedures may, in some instances, be partially influenced by the increase with age in a reflective strategy. This suggestion may help to explain puzzling differences in susceptibility to illusions. Some illusions, like the Ponzo, increase with age, others, like the Poggendorff, decrease with age (Leibowitz and Gwozdecki, 1967; Parrish, Lundy, and Leibowitz, 1968). It is suggested that the nature of the Ponzo illusion is such that the closer you attend to the stimulus, the *greater* the illusory effect. The nature of the Poggendorff illusion is such that the closer you attend to the stimulus materials, the *less* the illusory effect (see Fig 2).

In a recent study (Parrish, Lundy, and Leibowitz, 1968), adults were hypnotically age regressed to age 5 and were then administered the Ponzo and Poggendorff illusions. These regressed adults performed as children 5 to 10 years typically perform. The authors' preferred interpretation is that the perceptual process was altered by the hypnotic regression. However, it is possible that the regression merely created a set to respond impulsively. In the administration of the Ponzo illusion one vertical line remained fixed at 10.16 centimeters, while the second line (closer to the point of convergence) varied in length from 6.35 to 12.70 centimeters in 0.32-centimeter steps. The subject had to state which line was longer. An impulsive strategy might predispose a subject to alternate his answers from one line to another. Such

Fig 2 In the Ponzo illusion the vertical lines are equal but appear to be unequal In the Poggendorff illusion the diagonal portion is physically continuous but appear to be discontinuous

a strategy would make him appear as if he did not experience the illusion as strongly as a subject who compared each stimulus carefully

In the Poggendorff illusion the subject was required to adjust a bar so that the right half of the diagonal was in line with the left half. An impulsive person would not check his adjustment carefully, and hence might show an exaggerated illusion. The suggestion that these illusion results might be products of evaluation strategy rather than basic changes in perceptual processing is presented only as a possible interpretation. The intention is to alert the reader to at least consider the potential role of this dimension in all problem-solving contexts where the child must make a decision.

Relation of Reflection-Impulsivity to Early Behaviors Although anxiety over error is believed to be the primary incentive for a reflective strategy, there is a possibility that other factors can contribute to this disposition. It is of interest, moreover, to inquire into the early history of this disposition. How early can one detect and predict the signs of future reflectivity or impulsivity?

The Matching Familiar Figures Test (or any similar task involving uncertainty) may tap two different components: anxiety over error, on the one hand, and a dimension called "tempo of information processing," on the other. Some people appear to process information rapidly, others process information slowly, even in situations where the negative sanctions of public failure are lifted. The fast-

processing individual may actually assimilate more information per unit of time, or it may be that he only *appears* to process faster. He may be processing less minutely, matching to a grosser and less perfect standard, and therefore finishing in less time. One analogy uses the image of an electronic scanner programmed to locate all the combinations *AB* in a text. It could finish the task faster if it only searched for *As* rather than *ABs* and tallied a find each time. The fast rate would be the result of a looser standard of detection. Hence many false positives would be noted.

At the moment, there are not sufficient data to postulate a construct of "tempo of processing," independent of anxiety over error, that influences decision time. Moreover, even if this idea were viable, it is not clear whether the tempo differences are due to faster rates of processing or lower standards of detection. With this apology behind us, let us consider some data suggesting that something like a tempo dimension may exist during infancy and show predictive validity to the reflection-impulsivity dimension tested during the school years.

One argument for the existence of differences in tempo of processing is contained in the dramatic variation in rate of habituation to visual or auditory stimuli. Young infants show differential rates of habituation to visual stimuli such as representations of human faces, randomly generated nonsense designs, and novel mobiles. Rapid habituation to the faces could be the result of a firmer schema of the face. The closer the match of stimulus

to schema, the faster should be the habituation. However, individual differences in rate of habituation to the meaningless geometric designs or novel mobiles cannot be explained as a result of differential familiarity. It is unlikely that any of the infants had prior schemata for these novel stimuli. The rapidly habituating infants either established firm schemata for the novel stimuli at a faster rate, or then processing was less analytic (i.e., the internal schemata they created were grosser than the ones created by the slow habituating infants).

These hypotheses resemble those used in discussing the reflection-impulsivity dimension. It was suggested that impulsives either processed faster or had a grosser standard of equivalence. Would it be possible to obtain an early preview of the disposition to be reflective or impulsive at age 3 or 4 years from habituation rates during the first year? Preliminary data lend some tentative support to this idea.

As part of an ongoing longitudinal study by Kagan and his colleagues, 150 infants have been seen at ages 4, 8, 13, and 27 months. At 4 months, the infants viewed 16 presentations of 4 achromatic faces. Some children showed a rapid habituation of fixation time, others showed a more gradual habituation. At 8 months, the boys who had previously been rapid habituators showed a pattern of play with toys that can be characterized as having many short involvements. The slow habituating boys showed fewer, but longer involvements with the same toys. Rate of habituation at 4 months predicted tempo of play at 8 months. Moreover, boys who showed a fast tempo of play with the toys at both 8 and 13 months (many short involvements) were less attentive to visual stimuli at both these ages and more vigorous and excitable at 4 months. This evidence suggests the operation of a tempo factor (manifested in rate of satiation with toys and rate of habituation to visual stimuli) that is stable during the first year of life.

Some of these boys ($N = 52$) have been assessed at 27 months of age. The 27-month assessment variables include tempo of play with toys and decision times to two problem situations that contain response uncertainty (i.e., a specially devised embedded-figures test and a perceptual-conflict procedure).

There were positive intercorrelations (Repucci, 1968) among decision times on the two response-uncertainty tasks and a slow tempo of play (i.e., long epochs of involvement with the toys).

Moreover, the 2-year-old boys who showed long epochs of attentional involvement in a particular activity, in contrast to those who displayed short-duration involvements, showed a slower tempo of play at 8 months and more rapid habituation to visual stimuli at 4 months. In this analysis, the duration of each attentional involvement with an object at 27 months of age was quantified, and each child's distribution of time scores was cast into a frequency distribution. The seventy-fifth percentile (Q_3) value was chosen as the index of tempo of play. The range of seventy-fifth percentile values was from 30 to 187 seconds. For the total group of 52, there was a positive relation between slow tempo of play at 8 and 27 months ($\chi^2 = 3.8, p < .05$). When the 10 boys with the largest Q_3 values were compared with the 10 boys with the smallest Q_3 values (slow versus fast tempo), more of the slow tempo boys had a small number of act changes at 8 months of age ($p < .01$, exact test). The median value was 11 act changes for the slow tempo boys versus 30 act changes for the fast tempo boys at 8 months. More dramatic, however, is the fact that the 10 slow tempo boys showed a shallower habituation function for first fixation to achromatic faces at 4 months than did the fast tempo boys (see Fig. 3). These data give tentative support to the possibility that during the first year of life a tempo dimension is present which remains, at least for boys on the extremes of the dimension, somewhat stable throughout the second year.

The independent work of Pedersen and Wender (1968) is also supportive. Children 2½ years old were observed in a nursery school setting and were evaluated on their tendency to show long periods of attentional involvement with toys (This variable is very similar to the one coded in the play behavior at 27 months). Four years later, when these children were about 6½ years of age, each was administered the verbal and performance scales from the Wechsler Intelligence Scale for Children. The children who had shown prolonged periods of involvement with toys in the nursery school setting (i.e., slow tempo)

Fig 3 Differences in habituation of fixation time at 4 months for extreme groups on the tempo dimension at 27 months (boys) (First fixation to achromatic faces at 4 months)

performed better on the subtests that contained some response uncertainty (e.g., Picture Arrangement, Mazes) than the children who had shown short involvements. However, there were no differences between the two groups on the verbal scales. A slow tempo of play at 2½ years predicted a reflective attitude at age 6. Our longitudinal data suggest a positive relation between slow tempo of play and a reflective attitude at 2 years.

These data are still far from conclusive, but they offer some credibility to the hypothesis that children differ in the tempo of processing. Slow tempo children are more likely to become reflective, fast tempo children are more likely to become impulsive. The early display of these behaviors could be completely the product of differential experience, or it could be the partial product of biological differences among the infants. There is some reason to suspect that the differences in tempo and inhibition may have a genetic basis. For example, among 4-month-old males, the slow habituating infants tend to be larger, fatter, and smile more frequently than fast habituating infants. In addition, both body size and frequency of smiling during the first half year display greater similarity between monozygotic than between dizygotic twins. Further, two behavioral genetic studies implicate a tempo dimension. In one study, monozygotic and dizygotic boys and girls were observed in a free play situation at 8 months of age.

The tendency to show very few or many act changes during the opening 4 minutes of play—which is a partial index of inhibition—showed heritability (C. M. Reppucci, personal communication). In a second study, 61 pairs of identical and fraternal twin girls, aged 6 to 10 years, were observed in two experimental games and were interviewed. One of the critical variables was the time required for the child to decide which toy she wanted to play with after the testing session was over. The tendency to display short or long response times in this uncertain situation showed the best evidence of heritability. An overall rating of apprehensiveness (which was based, in part, on the response times) yielded an intraclass correlation of .88 for the monozygotic twins, but only .28 for the dizygotic twins (Scarr, 1966). Future studies will judge the fruitfulness of the idea that a disposition toward inhibition has a heritable basis. Existing information does not allow us to reject this notion out of hand (Gottesman, 1963).

Implementation of Hypotheses—The Deductive Phase

The complementary processes of “induction” and “deduction” have always been at the heart of cognitive work. Guilford (1959), among others, has emphasized the differential factorial structure of these two components of thought. On the other hand, in the natural sequence of thinking, the induction of similarities and hypotheses and the deduction of conclusions occur in close temporal contiguity, each nurturing the other. The induction that both air and ocean have permanent, spatially located currents, for example, is likely to be followed by the deduction that each flows in a preferred direction, each has turbulence, and each influences the weather. Of course, adequate deductive products also necessarily require a rich knowledge of rules.

A provocative example of individual differences in deductive problem solving is contained in a study of ethnic differences in profile of intellectual skills (Lesser, Fifer, and Clark, 1965). First-grade children from four ethnic groups in New York City (Chinese, Jewish, Negro, and Puerto Rican) were administered four tests: verbal ability, reasoning, number facility, and space conceptualization. Lower-class children in all four ethnic groups

had significantly poorer performances on all tasks than the middle-class children, but the profile of scores on the four tests was different for each of the ethnic groups. Although Jewish and Chinese children performed better than Negro and Puerto Rican children on most tests, the ipsative profiles were different. Jewish children gave their best performance on the verbal test and their poorest performance on the test of spatial ability. Chinese children showed the opposite pattern, performing poorly on the verbal test and best on the spatial test. The two less adequate groups—the Puerto Rican and Negro children—also differed from each other. The Negro pattern resembled that of the Jewish children—higher on verbal ability than on the other tests. The Puerto Rican child was lower on verbal ability than on the other skills. It is important to note that the profiles for each ethnic group were similar for both the lower- and middle-class children of that ethnic group, attesting to the importance of the genetic and experiential factors that are linked with ethnicity. This study was replicated in Boston (with Chinese and Negro children) with remarkably similar results.

There are at least two possible environmental interpretations of these provocative and consistent ethnic differences. One interpretation is that the Puerto Rican and Chinese children were exposed to a second language in the home, whereas the Negro and Jewish children were not. The former groups therefore might perform more poorly on verbal tests as a result of the interference produced by the language environment. A second and less likely interpretation assumes, first, that the vocabulary test had less response uncertainty than the reasoning, spatial, and number tests, and, second, that the Negro and Jewish children were temperamentally more impulsive than Chinese or Puerto Ricans. In this case, the pattern of findings could be explained as a result of differences in impulsivity among the ethnic groups.

Role of Family Experiences on Implementation. Some investigators have explored possible familial experiences associated with differential problem-solving abilities on verbal or spatial tasks. Freebeig and Payne (1967) have prepared a review of this literature. Bing (1963) found that fifth-grade children who were much better on spatial than on

verbal tasks had less interaction with their mothers than children with the opposite profile. Children with verbal skills superior to their spatial ability were dependent on a mother who was acceleratory and intrusive. The reader should note that the stereotype of the Jewish and Negro mother holds that she is generally more intrusive than the stereotyped Puerto Rican or Chinese mother. Ferguson and Maccoby (1966) have also reported that boys who are better in spatial than verbal ability are less aggressive and more withdrawn than boys with the opposite profile. Children who display a pattern in which numerical ability is superior to verbal or spatial skills tend to be popular and well liked (Ferguson and Maccoby, 1966) and are assertive and self-confident (D'Heurle, Melinger, and Haggard, 1959). Thus there is some concordance among the few studies that have investigated the relation among family experience, intellectual skills, and personality. It would appear that children who are more highly skilled on spatial than verbal tasks are more withdrawn and less aggressive than their age-mates, whereas those who are more highly skilled on verbal tasks tend to be more dependent than their peers.

Influence of Content and Mode of Presentation of the Problem. Personality factors are likely to influence quality of deductive sequences when the content of the problem has differential motivational relevance for the person. For example, Milton (1957, 1958) has found that college females perform better on deductive problems requiring arithmetic reasoning if the content of the question refers to feminine objects (i.e., deals with gardens and pies rather than guns and planets).

As with generation of hypotheses and concept sorting, the quality of deductive products is likely to be influenced by the mode of presentation of the problem. Since many deductive problems require the child to manipulate several bits of information, it is probable that oral versus written presentation will be an important determinant of quality of answers. Donaldson (1963) administered various deductive problems (e.g., matching, seriation) to children 10 to 14 years of age. An example is the following problem:

Five boys, Jack, Dick, James, Bob, and Tom go to five different schools in the same

town. The schools are called North School, South School, East School, West School, and Central School. Jack does not go to North, South, or Central School. Dick goes to West School. Bob does not go to North or Central School. Tom has never been inside Central School. Which school does Jack go to?

The problem was *read* to the child, but he could take notes if he wished. Donaldson analyzed the errors and reports of the children and attempted to diagnose the causes of the mistakes. Some children did not understand the problem, others were impulsive and did not check the validity of their final solution, others had difficulty with the negation in the problem. But the most frequent cause of error was a memory failure—the child had forgotten elements of the problem. If the problem had been presented in written form, it is likely that this cause of failure would have been eliminated.

The importance of mode of presentation has relevance to Piaget's assertion that children under 7 or 8 cannot perform class inclusion or seriation problems (Inhelder and Piaget, 1964). These problems are usually *read* aloud to the child. In order to solve the *simplest* class inclusion problem the child must hold in memory a minimum of *three* elements. It is possible that one basis for immature answers on these problems is memory failure.⁹

The number of bits of information that can be held in immediate memory increases with age over the period 3 to 10 years. It is reasonable to suppose that one of the many determinants of the "inferior" performance of preschool or kindergarten-age children on seriation and class inclusion problems is memory failure. Presentation modes that give the child continuous access to the elements of the problem might yield different results.

⁹ One of the authors has collected unpublished data on 6-year-old children in the first grade who were administered the following class inclusion problem: "There are 13 boys and 10 girls in the class. Are there more boys or more children?" When the problem was administered orally, less than 10% gave the answer, "More children." When the problem was presented in written form so that the child had access to all elements of the problem as long as he wished, 70% said, "More children."

We may conclude from this discussion that the answer produced by the child is a resultant of diverse forces. An incorrect answer could be the result of defective encoding of the problem, a failure in memory, generation of an incorrect solution hypothesis, insufficient evaluation of a solution hypothesis, inability to apply the proper deductive rule, or combinations of these failures. The nature of the final report does not typically provide information on its construction. Let us consider, in a bit more detail, the meaning of the "final answer."

The Significance of Public Performance

An answer—spoken, written, drawn, or acted out in gesture—is the datum from which we ordinarily infer cognitive process. The discussion thus far has been concerned primarily with the private mental processes of encoding, memory, generation of hypotheses, evaluation, and deduction. Psychology uses public performance to make wise guesses about these processes. This brief section addresses itself directly to the relation of performance to these cognitive constructs. How faithful is the public response to the inferred cognitive structure? Among the psycholinguists, this issue takes the form of the difference between linguistic competence and language performance. The transformational grammarian is concerned primarily with competence and often seems too little concerned with language behavior. At one extreme, it is acknowledged that absence of a particular performance is always ambiguous as to meaning and cannot be taken as a reflection of the presence or absence of a structure. But once a behavior occurs it is natural to ask what structure it serves or represents. If a child says "sheeps" for "sheep," or "wented" instead of "went," does this error necessarily mean that he could not tell you that "went" is correct and "wented" incorrect?

In many instances, incorrect performance does not signify deficient cognitions. Consider an extreme example. If a child of 4 is asked to draw a man as faithfully as possible, he is likely to draw the man's arms attached to the head. However, if the child is shown a drawing of a well-formed man and a drawing of one with arms emanating from the head and is asked to point to "the man," the child quickly points to the correct representation.

Competence leads performance. At a less obvious level, some psychologists assume that if the child cannot reproduce a nonsense design (e.g., an item from the Bender-Gestalt Test), he must have a perceptual deficit. However, Birch and Lefford (1967) have shown, in elegant fashion, that a child who cannot reproduce a design has no trouble identifying the correct design when it is presented along with a group of similar ones. Maccoby and Bee (1965) have also addressed themselves to this issue.

In the Birch-Lefford work, children 5 to 11 years of age were asked to reproduce triangles and diamonds under five different conditions, ranging from no visual support to considerable visual support. As expected, the quality of these reproductions increased with age. These children were also given a series of purely perceptual tasks, where they had to match a geometric form to a standard (perceptual analysis) or judge the equivalence of a geometric form with a set of its component elements (perceptual synthesis). Performance on both perceptual tasks increased with age. However, the correlations, at any age, between each of the two perceptual performances and quality of reproduction were about .20 or lower. The ability, or inability, to draw a simple geometric form is relatively independent of the ability to discriminate it from a set of similar forms—that is, to perceive it correctly. The goal-directed motor action is not a faithful index of cognitive competence. Of course, when age groups were pooled, a positive association emerged between quality of reproduction and perceptual performance. But these positive correlations are likely to be a derivative of more central growth parameters that produce increases in quality of all performances. This study provides the best empirical demonstration of the fact that perceptual-motor performance or graphic reproduction of events provides a distorted view of cognitive competence, in much the same manner that quality of speech is unfaithful to richness of thought.

Children also differ in their preferred behavioral reaction to difficult problem situations. Some persist, whereas others directly refuse to go on with the tasks, still others become quietly passive and neither speak nor act. A recent study of 3-year-olds compared lower-class Puerto Rican children with mid-

dle-class Caucasian children (Hertzog et al., 1968). There were two interesting differences between the groups in their behavioral reaction to intellectual problems. The middle-class children were more likely to work at a problem than the Puerto Rican children. Moreover, when problems became difficult, the middle-class children were more likely to overtly shake their heads, say they couldn't do it, or push the material away. The Puerto Rican children frequently sat passively, saying or doing nothing. These behavioral differences held, even when pairs of children were matched on intellectual ability. Differences in quality or style of public performance, although striking, may be misleading indexes of competence. These isolated examples may be the rule rather than exceptions.

Another category of behavior includes spontaneous responses to external stimuli, sometimes called released behaviors by comparative psychologists. A child hits a ball, grasps a mallet, pounds clay, or smears paint. These behaviors are not untarnished reflections of cognitive structure, for each is fitted specifically to the target stimulus. The hitting of the ball with the full hand, the grasping of the mallet, and the pounding of the clay may be of the same dynamic significance. Each appears different to the observer because the act must be accommodated to the external object. Each behavior is a result of cognitive structure and immediate context. In order to infer the nature of the structure one has to separate and assess these vectors, a task for which psychology does not yet possess sufficiently sensitive procedures.

In sum, the child's drawings, speech, and test responses are under the supervision of many factors. A careless attitude toward a drawing can yield a poor reproduction, an inability to coordinate lines can yield a gross distortion of a public event, immature syntax can destroy effective communication of a well-formed idea. Psychology is forced to remain tied to public behavior as the major data base for inferring cognitive structure. Test performance is the combined result of motivation, language, expectancy of success, preferred strategies for perceptual analysis, and reflection-impulsivity, to name only a few. Without separate controls (statistical or experimental) or independent assessments of these constructs, the final performance is an

indeterminate index of each of them, or, in other words, a unique composite of them all.¹⁰ The invention of analytic procedures for separate evaluation of the qualitatively different components of a public performance deserves the highest priority in the future.

Field Dependence-Independence

Although we have referred to the work of the Witkin group in passing, its coherence, influence, and scope warrant detailed treatment. In many respects, Witkin's research can be considered the most serious attempt at construct validation with respect to a dimension of cognitive functioning. The following sections discuss the research in the Witkin tradition with special emphasis upon the criterion measures, developmental changes, relationships with ability indices, body concept, sex differences, personality correlates, social behavior, antecedents in parent-child interaction, and cross-cultural evidence.

Criterion Measures The Witkin group has relied heavily on three procedures for assessing an individual's level of field independence-dependence, alternatively called field articulation-diffuseness, analytic-global functioning, psychological differentiation.¹¹ These

three procedures are the Body Adjustment Test (BAT), the Rod-and-Frame Test (RFT), and the Embedded Figures Test (EFT). They constitute the core of Witkin's assessment program. We shall describe them in summary form. Detailed descriptions of the three procedures are available in the two Witkin et al. (1954, 1962) volumes.¹²

In the case of the Body Adjustment Test (BAT), the subject is seated in a tilted chair within a tilted room, and his task is to adjust his chair to the true vertical while the room remains tilted. The deviation of the chair's adjusted position from the true upright constitutes the subject's score.

In the Rod-and-Frame Test (RFT), the subject is seated in a completely darkened room facing a luminous rod suspended within a luminous frame. The subject is required to adjust the rod to the true vertical, when his body is tilted or upright, and when the rod and frame are tilted in the same or opposite directions. The subject's score is the extent of absolute deviation of the rod setting from the true upright.

Finally, the Embedded Figures Test (EFT) consists of a series of complex geometric figures in which a series of simple figures is embedded. The test derives from an earlier instrument (Gottschaldt, 1926), but Witkin has made his test more difficult by superimposing colored patterns over the simpler achromatic Gottschaldt figures. The subject's score on the EFT represents the mean amount of time required to locate each of the simple figures.

Scores derived from the BAT, RFT, and EFT satisfy most psychometric standards for reliability. Split-half reliabilities have ranged in the low 80s to high 90s, and test-retest data over a period of 3 years have produced reliability coefficients ranging from the 60s to the 80s.

A more fundamental question concerns the functioning in Kagan's sense for those tasks (e.g., conceptual learning) where analytic functioning is required for good performance, but not for those tasks (e.g., sorting) in which it is a stylistic preference (Messick and Fritzky, 1963; Wachtel, 1968).

¹² Sometimes the Figure Drawing Test is treated as a criterion measure, at other times as a correlate. For our purposes, the test will be considered a correlate in the domain of body-image

¹⁰ This dilemma is inherent in all the empirical sciences. The notion that a physical measurement always invokes the disturbance of the quantity being measured has long been appreciated in physics and found its most classic expression in Heisenberg's law of indeterminacy. However, earlier in the century there was considerable resistance to this idea.

¹¹ We shall use the various labels interchangeably with the exception of "psychological differentiation," which reflects a particular theoretical conception of the phenomena under investigation, whereas the other constructs are more operationally descriptive and more directly tied to the actual performance of the subjects. Since there is considerable controversy and ambiguity surrounding the construct of differentiation, the acceptance of Witkin's conceptualization would clearly prejudice the issue. It should be further noted that Witkin's research on analytic functioning can be distinguished from that of Kagan (as discussed previously) with regard to both conceptualization and measurement procedures. A critical discussion of these differences can be found in Wallach (1962). Empirical evidence has been obtained on adult subjects, suggesting that Witkin's EFT measure may relate to analytic

relationships among the three indices of field dependence. Recent evidence (Witkin, Goodenough, and Karp, 1967) has indicated a substantial level of consistency for cross-sectional groups (age 8 to 21). The vast number of significantly positive correlations found in this work provides considerable justification for combining the three separate indices into a composite perceptual index. This procedure is typically followed in the work of the Witkin group.

This procedure may not be justifiable in non-Western cultures, however. Wober (1966, 1967) found no relation between EFT and RFT performances in Nigerian men. This result is explained on the basis of American-African differences in "sensotypes." West African cultures place less emphasis upon visual analysis than do Western cultures and concentrate more on the proprioceptive skills involved in dancing and other forms of physical expressiveness. Since the RFT has proprioceptive features, whereas the EFT is strictly visual, the RFT may be a better index of analytic ability in certain West African cultures. In the Wober studies, RFT performance was significantly related to "job efficiency," whereas the EFT was related to educational level. The last relation reflects the test-like properties of the EFT. Consistent with Wober's observations of Nigerians are Gruen's (1955) findings on professional American dancers. For the latter group, RFT measures with a proprioceptive component—that is, with body tilted—were unrelated to EFT scores.

Nevertheless, the measures developed by Witkin and his associates are reliable and cohere with one another in unselected American subjects. This raises the important issue of the psychological basis for the coherence. A series of alternative explanatory constructs has been proposed, with all but one eventually being rejected on empirical grounds. Thus Witkin has offered evidence against interpretations based on "perceptual accuracy" and "body sensitivity." Relevant to the latter, Witkin observed that performance in the BAT when the subject closed his eyes was not significantly related to his performance with eyes open. Obviously, open or closed eyes should make little difference to a body-sensitivity hypothesis. In due course, the current interpretation was accepted—the com-

mon element in the three critical measures is the ability to overcome an embedding context. The BAT, RFT, and EFT all require that something—body, rod, and geometric design, respectively—be separated from the field or context in which it is embedded. Subsequently, Karp (1963) has demonstrated that the critical attribute of the item-field relation is embeddedness rather than distraction. Performance on a series of tasks with distracting contexts generated one factor, whereas a different factor was found to load the three "embedding" tests (BAT, RFT, and EFT). Also congruent with the embedding notion is the indication that subjects in the tilted-room-tilted-chair situation, when asked to adjust the room rather than their bodies to the upright, do not perform consistently in the two tasks. Scores derived from the Room Adjustment Test (RAT)—deviation of the position of the adjusted room from the true vertical—were essentially unrelated to BAT scores and the other indices of differentiation. Witkin et al. (1962) have noted that the task of adjusting the room presents no problem of an item embedded in a field. Rather, the subject has essentially been asked to cope directly with the position of the field itself.

Brief mention might also be made of the fact that RFT scores proved to be most satisfactory as an index when the chair was not tilted (Witkin et al., 1967). The Witkin group traces the difficulty under chair-tilted conditions to Muller's (1916) E-effect, according to which subjects tend to perceive the upright as displaced in the direction opposite to body tilt. It is not very clear, however, why individual differences in the E-effect should stand apart from differences in extent of field dependence.

From the perspective of the present chapter, it is especially important to note that the various procedures described have been employed with children as young as 10 years of age for the EFT and 8 years of age for the BAT and RFT. A children's form of the Embedded Figures Test (CHEF) appropriate for subjects as young as 5 years of age has been developed by Goodenough and Eagle (1963). In this test, meaningful complex figures (e.g., car, man, boat) are substituted for the abstract geometric designs of the standard EFT. Again, the child is expected

to locate a simple figure embedded within the whole, where the whole resembles a giant jigsaw puzzle. A knob protrudes from each of the separate pieces of the puzzle, but only the piece corresponding to the correct simple figure is removable when the child pulls the knob. The child's score consists of the number of items on which the correct knob is pulled first.

The reliability of the CHEF in 6- to 9-year-olds ranged from the high 50s to the low 80s. For a sample of 10-year-olds, the CHEF yielded statistically significant correlations of .46, .70, and .63 with the BAT, RFT, and EFT, respectively. Thus the CHEF appears to be a valid index of field dependence at the 10-year age level, although this does not insure, of course, that the same degree of validity applies for younger children. Some support for such validity may be derived from the evidence that CHEF performance significantly improved from age 5 to age 8. Note, finally, that another version of a children's embedded-figures test (CEFT) is available whose psychometric properties are somewhat superior to the Goodenough-Eagle version (see Karp and Konstadt, 1963).

Developmental Change In the preceding section, high test-retest correlations were offered as evidence for the reliability of the various field-dependence indices. As the time between test and retest increases, the correlations are informative with respect to both the reliability of the instrument and the relative stability of field-dependence level during the course of development. Recently, Witkin et al. (1967) have offered coefficients of stability for two longitudinal groups, one tested at ages 8 and 13, the other tested at ages 10, 14, 17, and 24. For both groups, all of the correlations were significant and substantial, with r s ranging from .48 to .92. Hence a preadolescent child classified as field-dependent or field-independent (or of in-between status) has a quite high probability of being identically classified as a young adult.

The foregoing evidence implies that the *relative* position of an individual on Witkin's perceptual dimension remains fairly constant over a time span of as much as 14 years. Is such stability also obtained in regard to an individual's *absolute* level over time? Witkin et al. (1967) explored this question in both cross-sectional and longitudinal samples

of children, adolescents, and young adults. In the case of the cross-sectional data, the developmental curves reveal a progressive improvement in performance with increasing age up to 17, followed by a slight decline through age 21. This increase and subsequent decrease in level of field independence with chronological age was observed for all three indices—BAT, RFT, and EFT. In the case of the longitudinal groups, only the RFT data were considered, since there is evidence for learning effects—knowledge of results being available to subjects—in both the BAT and EFT (see Goldstein and Chance, 1965; Witkin et al., 1954). As in the case of the cross-sectional data, the longitudinal evidence also showed that maximal field independence was achieved at age 17. Unlike the cross-sectional evidence, however, no decline in RFT scores from age 17 to age 24 was found in the longitudinal data. Witkin et al. attribute the difference in separate sets of data to the character of the young adults employed in the cross-sectional studies. Most were students attending a local college and living at home, characteristics presumed to be associated with lower field-independence levels. This interpretation based on selection bias appears to be very reasonable. Though a decline in field independence does seem to occur very late in life—geriatric groups were highly field dependent (Schwartz and Karp, 1967)—it is most unlikely that such a decline would begin in the early 20s.

In considering the implications of their developmental findings, Witkin and his associates noted that both the family and the overall environmental settings of the longitudinal subjects were fairly stable over the 14-year period in which they were studied. Nevertheless, as those authors have also emphasized, the period from age 10 to 24 is characterized by great personal change, including such events as puberty, lessened dependence on the family, choice of occupation, and, sometimes, marriage and the assumption of family responsibilities. Any psychological dimension that manifests so high a level of stability through so turbulent a period of life must surely be ranked as one of the most powerful continuities in the domain of human development, comparable in many respects to the observed stability of the IQ. However, one should not lose sight of the fact that the

stability of field independence is basically interindividual, not intraindividual. In other words, the subject maintains his position relative to others. At the same time he is progressively increasing in field independence.

In a critique of Witkin's work, Zigler (1963a, 1963b) has unfavorably contrasted Witkin's emphasis upon continuity and stability with Werner's and Piaget's stress upon developmental change. In actual fact, the disagreement may be more apparent than real, for most of Witkin's research has employed children who have reached the age where many of the fundamental cognitive changes of development have already taken place. Under any circumstances, however, it must be acknowledged that the course of development is distinguished by both continuities and discontinuities. A comprehensive developmental theory should be able to incorporate both the dimensional stability observed by the Witkin group and the changes in cognitive organization observed by Werner and by Piaget. There is no a priori reason why one should be deemed more important than the other.

Relationships with Ability. One of the most controversial aspects of Witkin's research concerns the role played by intelligence with respect to performance on the BAT, RFT, and EFT. Evidence is available (Witkin et al., 1962) for 10- and 12-year-olds of significant correlations between field independence, on the one hand, and the Stanford-Binet and WISC total IQs, on the other. However, in the case of the WISC specifically, the correlations were somewhat higher with the performance scale than with the verbal scale. With the view toward discovering whether the positive link between total IQ and field independence might be "carried by" specific subtests of the WISC, a factor analysis was performed on a variety of cognitive tasks including the WISC subtests and the three indices of field independence (Goodenough and Karp, 1961). Three major factors emerged that were reasonably matched for 10- and 12-year-olds. The pattern of loadings of the various WISC subtests on the three factors corresponded in many respects to the outcomes of a previous factor analysis of the WISC (Cohen, 1959). Factor I was labeled "verbal comprehension" by virtue of the substantial loadings for the Vocabulary, Information, and

Comprehension subtests. Factor II was designated "attention-concentration," given the substantial loadings for Digit Span, Arithmetic, and Coding. Finally, Factor III was assigned the label "analytical field approach" on the basis of substantial loadings for Picture Completion, Block Design, and Object Assembly. The RFT, BAT, and EFT also yielded fairly high loadings on Factor III.

Witkin et al. (1962) present a convincing case for commonalities between the three WISC subtests loading Factor III and the three field-independence indices on the basis that all require the overcoming of an embedding context. It is, in fact, the evidence of such correspondences across the intellectual and perceptual domains that prompted the redefinition of the major construct at issue as "analytic versus global field approach." Field dependence-independence is presently considered by the Witkin group as the perceptual component of the more pervasive cognitive style of analytic-global functioning.

Given the evidence that the field-dependence indices are negligibly loaded on the "verbal comprehension" and "attention-concentration" factors, an argument can be made against Zigler's (1963a, 1963b) contention that the significant link between field-dependence measures and *general* intelligence mediates most of the findings reported in *Psychological Differentiation*. It is doubtful whether our understanding would be advanced by reducing the constructs of field independence and analytic functioning to an amorphous "general intelligence" construct which bears no conceptual relationship to any major psychological theory. As long as most intelligence tests are constructed on the basis of intuitive hunch and psychometric item analysis, scores on such tests can hardly serve as the cornerstone of a major theoretical effort. We are not implying, of course, that a *g* factor of intelligence does not exist. In fact, we sympathize with Zigler's suggestion that *g* should serve as a control variable when examining relations between field-dependence indices and other variables. The factor-analytic findings obtained by Cohen (1959) do show that the three WISC subtests loaded on Witkin's "analytical field approach" factor are also substantially loaded on *g*. Hence it would be of considerable interest to know how the

impressive array of findings obtained by the Witkin group would be affected by a statistical control for the *g* factor

More disturbing than the possible influence of *g* on analytic functioning is the evidence that such functioning may not be as independent of verbal skills as the Witkin group has claimed. Crandall and Smkeldam (1964) obtained significant correlations in 10- to 12-year-olds among field independence and the three WISC subtests loading the "verbal comprehension" factor. Comparable results were found for young adults by Wachtel (1968). Note further that the intelligence subtest most closely related to analytic functioning—Block Design—correlates between .27 and .54 with the Vocabulary subtest in normative data presented by Wechsler (1949, 1967). Holtzman (1965) reports similar evidence. Although a case can be made against the partialling out of the *g* factor on the grounds that some of its components are determined by the analytic dimension (and Witkin has tried to make such a case), no such argument can be applied where verbal skills are at issue. The Witkin group has rejected the possibility of any theoretical bridge between analytic functioning and the WISC verbal cluster. Since field independence is sometimes empirically linked to verbal IQ, however, the control of verbal IQ becomes imperative when field independence is related to other variables.

We conclude our discussion of the ability area with a consideration of relations between mode of field approach and verbal skills considered more generally. Witkin et al. (1962) demonstrated that the child's "verbal expressiveness" as manifested in clinical interviews and TAT story telling bears no significant relationship to mode of field approach. However, "cognitive clarity" indices, which presumably circumvent the dimension of verbal expressiveness, were significantly related to field-independent functioning. "Cognitive clarity" implies nothing more than the ability of the child to make his thoughts and ideas intelligible to the interviewer.

Of particular interest in the present context is the question of whether a verbal task with the property of embeddedness taps the kind of cognitive style represented by Witkin's dimension of analytic-global functioning. Such a task was employed in a study by Podell and Phillips (1959). It made use of an ana-

gram format in which already meaningful words had to be broken up in order to form new words. Performance on the task was not related to spatial decontextualization, a factor quite similar to Witkin's perceptual mode-of-field-approach index. Related to this outcome is the evidence that another verbal-embeddedness task—Camouflaged Words—was not related to the "adaptive-flexibility" factor delineated by Guilford, Frick, Christensen, and Merrifield (1957). This factor includes a variety of perceptual-restructuring tasks of the type used by Duncker (1945) and others. The Gottschaldt test also loads on the factor. Karp (1963) has subsequently shown that Guilford's adaptive-flexibility factor is strongly related to Witkin's field-independence measures.

In sum, verbal tests, even under conditions where they require that an embedding context be overcome, manifest no relation to mode of field approach. It is evident, then, that "embeddedness" tasks with spatial, configural properties are most relevant to the kind of analytic functioning with which Witkin and his associates have been concerned. The implication drawn by the Witkin group from their empirical evidence is that most verbal processes are of little relevance to psychological differentiation. It is this assertion that has provoked the most vigorous dissent from Zigler, who has noted that verbal ability (as reflected in mental age) is a prime indicator of level of differentiation in most developmental theories. The relegation of verbal skills to a secondary role by the Witkin group forms the basis of Zigler's attack on their theoretical conceptualization of the differentiation construct. Zigler argues that the procedures devised by Witkin and his associates reflect "decontextualization," a construct that can be subsumed under differentiation at a considerably lower level of abstraction. We shall return to this point later in our final summary and evaluation of Witkin's contribution.

Body Concept In our review of the work of the Witkin group thus far, we have focused on procedures that assess the child's capacity to differentiate a field and to differentiate his body from a field. The present section concerns the child's articulation of the body concept itself, as reflected in drawings of the human figure. The cognitive, intellectual aspects of human figure drawing have been

recognized for a long time. In 1926, F. L. Goodenough published the Draw-a-Man Scale as a test of nonverbal intelligence. In contrast to this intellectual emphasis, the initial use of figure-drawing procedures by Witkin and his associates (Witkin et al., 1954) was strongly influenced by Machover's (1949) approach. Machover viewed figure drawing as a projective test capable of assessing such motivational constructs as anxiety, sexual identification, and self-confidence. In their more recent work, Witkin et al. (1962) have employed the figure-drawing technique exclusively for the purpose of measuring the level of primitivity-sophistication of the child's productions; this is considerably closer to Goodenough's original conception.

Assessment of the sophistication of body concept in Witkin et al. (1962) was based on "the form level of the drawings, the extent of identity and sex differentiation of the figures, and the level of detailing" (pp. 119-121). Judges were required to use the foregoing three categories in making a global rating of sophistication of body concept on a five-point scale. Satisfactory interjudge reliability was obtained ($r = .84$). Highly significant correlations in 10- and 12-year-old boys were found between the sophistication-scale scores and perceptual index scores (a composite of BAT, RFT, and EFT). Sophistication of body concept was also significantly related to the analytic cluster of WISC subtests, but unrelated to the WISC verbal cluster.

In sum, fairly strong evidence exists to support the proposition that children with an analytic field approach have more articulated body drawings than do children with a global field approach. On the other hand, it must be granted that definitive evidence is lacking to support the claim that the child's figure drawings actually reflect his conception of his own body. In fact, the pattern of correlations with mode of field approach did not differ very much when Goodenough's intelligence scale was substituted for Witkin's sophistication-of-body-concept scale. Indeed, the two scales were highly correlated ($r = .74, p < .01$). Hence a case can be made that the figure drawings are really tapping a facet of nonverbal intelligence.

Personality and Motivational Correlates In the earlier phase of their work, Witkin et al. (1954) conceived of an "active, coping" ver-

sus "passive, submissive" relation to the environment as the personality dimension most closely linked to field-independent versus field-dependent functioning, respectively. The more recent book (Witkin et al., 1962) de-emphasizes the importance of a general activity-passivity dimension. Diverse forms of activity are recognized. Some are presumed to be relevant to field independence, others are presumed to be irrelevant. Assigned to the irrelevant category is the type of activity represented by high energy level and/or motoric output. Where activity assumes the hyperkinetic form suggestive of lack of impulse control, Witkin predicts a global field approach. No empirical evidence relevant to this point is offered, however. Where activity assumes the character of striving and assertiveness toward well-formulated goals, a relationship with an analytic field approach is anticipated. A TAT assessment of the preceding type of "active attitude" was carried out in 10-year-old boys. Stories were scored for assertiveness and counteraction (overcoming adversity). For neither variable was a stable relation with field independence obtained.

Witkin and his associates (1962) have also tested the proposition that an active or passive attitude would be expressed in the characteristic posture of the body. One of the samples of 10-year-old boys was photographed, with no special instructions given as to the pose to be assumed. With the face blotted out, the posture of each boy photographed was evaluated on a four-point scale ranging from "active-assertive" stance at one extreme to "passive" stance at the other. These ratings were significantly correlated with the field-independence composite, suggesting that "children with an analytic field approach tend to give evidence of greater 'readiness for action' than children with a global approach" (p. 183).

Although the findings from this (Witkin et al., 1962) study tend to confirm the hypothesized link between activity-passivity and field independence-field dependence, the evidence considered as a whole is unimpressive. It should be emphasized, however, that Witkin and his associates have clearly relinquished any claim to a simple, direct association of activity-passivity in the behavioral sense with mode of field approach. Activity-passivity in overt behavior is multidetermined,

and, further, outwardly similar behaviors will often have quite different psychological meanings. It is hardly surprising, then, that Witkin's earlier (1954) formulation regarding the activity-passivity dimension has not held up well under subsequent empirical examination.

Another attempt to show that modes of field approach reflect deep-seated personality dispositions is found in the evidence concerning defensive structures. Witkin et al (1962), on the basis of their "differentiation" hypothesis, proposed that children with an analytic field approach would tend to employ "complex, specialized defenses" (e.g., intellectualization, isolation), whereas children inclined toward a global field approach would tend toward the use of simple, primitive defenses (e.g., repression, denial). Particular defenses and modes of field approach are presumed to develop in closely interlocking fashion. Thus highly structured defenses would be expected to contribute toward impulse control, which, in turn, might relate to the kind of attention regulation necessary to perform in an analytic manner. Correspondingly, where primitive denial is a favored mechanism of defense, one might well expect the child to structure his experience in a vague, global manner.

The degree of structure of controls and defenses was evaluated in a sample of 10-year-old boys by means of a blind clinical analysis of protocols from three projective tests—the Rorschach, the TAT, and a figure-drawing procedure. The 23 boys under study were classified on the basis of a five-point scale, ranging from low to high degree of defensive structure. Correlating these ratings against the perceptual-index scores yielded a highly significant r of .61. This finding is supportive of Witkin's hypothesis, but one still must consider the validity question: Do the clinical projective-test ratings actually reflect the child's defensive structure?

Comparable validity problems arise with respect to further tests relating to modes of handling aggression and denial of aggressive stimuli in TAT imagery. According to the Witkin group, field-dependent boys displayed more uncontrolled aggression and at the same time were less likely to perceive salient aggressive stimuli in the TAT cards than their field-independent peers. There is, of course, something of a contradiction in this outcome,

which receives no acknowledgment from the Witkin group. One might argue that denial occurs where the stimuli, though emotionally provocative, are relatively mild, whereas more impelling stimuli make denial impossible and consequently produce a breakdown in control mechanisms. The validity problem arises, however, in the question of whether judges are, in fact, rating the protocols on the basis of maturity or personality integration. The latter characteristics were claimed to be irrelevant to the analytic-global style elsewhere in the Witkin et al (1962) volume. Yet all of the projective data reported appear to attribute greater psychopathology to the field-dependent than to the field-independent child. Part of the reason for this is the absence of any empirical inquiry into the hypothesized link between analytic functioning and employment of such specialized defenses as intellectualization and isolation.

Social Behavior Scattered through both of the published volumes by Witkin and his associates are numerous references to studies that have reported differences in the social behavior of field independents and field dependents. The large bulk of this research is based upon adult samples. More recently, however, there have been a few published papers concerned with the social behavior of children in relation to their status on the field-dependence dimension.

Where adults are concerned (Witkin et al, 1954), there is evidence suggesting that field dependence in perception is associated with passive, dependent interpersonal behavior. Crandall and Sinkeldam (1964) have explored this issue in the case of a sample of children in the 6 to 12 age range. Both dependent and achievement behaviors in free-play social situations were assessed. A relation between an achievement orientation and perceptual field independence was anticipated, on the grounds that the EFT measure of perceptual field independence (the measure employed by Crandall and Sinkeldam) was saturated with achievement cues. Hence achievement-oriented children would be expected to perform at a higher level on the EFT than those children less preoccupied with achievement. Three types of social behavior indicative of dependence on adults—instrumental help seeking, affection seeking, and recognition-approval seeking—were ex-

amined in relation to EFT performance. Similarly, Crandall and Sinkeldam explored the relation between field independence and four kinds of achievement behavior—concern with motor mastery, time alone on tasks, independent achievement efforts, and task persistence. Since the three indices of dependent behavior and the four indices of achievement behavior yielded two relatively homogeneous clusters (in terms of the pattern of correlations), overall dependency and achievement scores were also derived.

One methodological feature of the Crandall-Sinkeldam study is especially worthy of note. Since IQ was significantly correlated with field independence and with some of the social behavior ratings, the major relationships at issue were examined with IQ controlled by means of partial-correlation procedures. It will be recalled that the Witkin group did not employ such procedures, a fact that served as one of the major criticisms leveled against their work by Zigler. With both age and intelligence controlled, dependent social behavior was only minimally related to perceptual field dependence.¹³ The dimension of "affection seeking from adults" yielded a marginally significant correlation with EFT performance. From one point of view, such findings can be considered as damaging the construct validity of the field-dependence construct. On the other hand, Witkin has stressed the multideterminacy of overt social behavior. As Witkin et al. (1962) have noted

In children recognition-seeking may signify primarily a need for support from others and so be interpreted as socially dependent behavior, or it may signify primarily a strong interest in mastery. In the conceptualization of socially dependent behavior it seems useful to delineate the contributions of extent of sense of separate identity, active-vs-passive attitude,

nature of emotional involvement with others, and kinds of motivation (p. 187).

The achievement behavior variables, in contrast to the variables of dependent behavior, were substantially related to perceptual field independence (with age and IQ statistically controlled). Only the dimension of "time alone on tasks" failed to share in the overall relationship.

Responding to a suggestion by Witkin that the meaning of the testing situation may not be the same for younger and older children, Crandall and Sinkeldam report separate analyses for these groups based on a median age split. It was expected that the testing situation might prove to be difficult for younger children, thereby evoking dependency needs; on the other hand, older children, being more accustomed to testing, might bring an achievement orientation to bear on the task. The results generally did not support Witkin's suggestion. Dependent social behavior was unrelated to field dependence in both age groups, and achievement-oriented behavior was related to field independence in both younger and older children.

As we have indicated, the absence of an association between perceptual field dependence and dependence in free-play social behavior constitutes something of a challenge to Witkin's position. We also observed, however, that the free-play situation may not be an ideal setting for testing the hypothesis at issue, given the multidetermined nature of behavior under such conditions. A study by Konstadt and Forman (1965) has examined the effects of field dependence upon dependency-related behavior in an experimentally controlled setting. Fourth-grade children selected from the extremes of the CEFT score distribution were given a letter cancellation test under conditions of experimenter approval and disapproval. Statements of approval or disapproval were offered orally by the experimenter at frequent intervals during the testing session. The statements had no connection with the subjects' levels of performance on the assigned task. Konstadt and Forman anticipated that the field-dependent children would exceed their field-independent peers in sensitivity to the experimental conditions. It was expected that such differential

¹³ It can also be argued that field independence affects level of performance on particular subtests of intelligence, and therefore controlling for total IQ is not entirely justified. The Witkin group, of course, would favor such an argument. Within the context of the Crandall-Sinkeldam findings, however, the foregoing issue is not too important, for the overall pattern of results does not change much when IQ is statistically controlled.

sensitivity would be manifested both in level of performance on the task and in the orientation toward peers and experimenters as reflected in looking behavior during task performance

The results were generally consistent with the preceding hypotheses. There was a significant tendency in the direction of poorer performance from field-dependent children under disapproval relative to approval conditions. No such discrepancy was obtained in the case of the field-independent children. With regard to the number of times subjects gazed at some other person in the room, there was significantly more "looking" behavior for field-dependent than for field-independent children, but only under the condition of experimenter disapproval. A significant interaction effect with condition order was also obtained. Field-dependent children under the disapproval condition looked at others more when they experienced this condition *after* having experienced approval than when the order of the conditions was reversed.

In sum, both the test-taking and the looking behavior of the children suggested that field dependents were more disrupted by an unfavorable emotional climate than were field independents. The dependent group appears to be more externally directed, in the sense that their cognitive-affective behavior is differentially influenced by the positive or negative social cues emitted by others. Thus in order to demonstrate a relationship between field dependence and behavioral dependency it was necessary to create a situation in which social rewards were withdrawn or replaced by punishments. Such circumstances are not ordinarily found in free-play, and this may account, in part, for the differing outcomes of the Crandall-Sinkeldam and Konstadt-Forman studies.

Antecedents Consider now the evidence offered by Dyk and Witkin (1965) and Witkin et al. (1962) on antecedents of field dependence in parent-child relationships. Interviews were conducted with the mothers of the boys under study. For one of the samples, the boys were 14 years of age when their mothers were interviewed, in the other two samples, the mothers were interviewed when their sons were 10 years old. A variety of indicators

was employed for evaluating the interview data. The characteristics of the mother as a person and the nature of her interaction with her son were among the areas measured. In the former category, the major indicators concerned the mother's sense of self-assurance and self-realization in life. In regard to interaction with the child, the indicators focused on training for independence and training for control of aggressive behavior. Ratings made on the separate indicators were used to make an overall global judgment of the mother as "fostering or inhibiting differentiation", that is, mothers were placed in one of two groups corresponding to these classifications. Where there were conflicting signs for the separate indicators, the global judgment was based on the "overall impact of the evidence."

Correlations between the sons' perceptual index scores and the global rating of the interview data provided by mothers were statistically significant and very high. The point biserial r s were .85 and .65 in the 10-year-old samples and .82 in the 14-year-old sample. It would thus appear that mothers of field-independent and field-dependent boys interact with their children in a manner that fosters one or the other cognitive orientation. The exceptionally high magnitudes of the correlations, however, arouse suspicion that the relationships noted may have some spurious basis. Zigler has, in fact, offered an interpretation along such lines. Given the fact that the interviewer necessarily had to discuss the son's behavior with the mother, it was highly probable that the interviewer could accurately categorize the child as field dependent or field independent. Such an inference would come naturally to a trained rater or interviewer and could readily have biased the global judgments in a direction consistent with the judgment of the child's status on the field-dependence dimension. Although there is likely to be some relation between the mother's attitudes and behavior, on the one hand, and her child's style of cognitive functioning, on the other, the actual magnitude of such relationships must remain uncertain. It is, of course, no simple matter to remove this type of contamination as long as the interviewer wishes to obtain information from the mother concerning her child-rearing attitudes and methods. A step in the right direction would

be a systematic analysis of the individual indicators that comprise the final global judgment

Witkin and his associates (1962) have indicated some awareness of the difficulties surrounding the use of global impressions and have accordingly employed additional methods to ascertain the influence of the mother on the cognitive functioning of her son. Thus the field-dependence level of mothers was assessed and then examined in relation to that of their own sons. The Witkin group anticipated a positive relationship between the field-dependence scores for mother-son pairs. The basis for such a hypothesis rested on the assumption that field-dependent mothers, by virtue of their attitudes and behavior, would create the kind of home climate likely to inhibit the development of field independence in their sons, whereas mothers who were field independent would foster differentiation in their sons. Confirmation of the hypothesis would be a fact of considerable importance, for, unlike the interview data, there is no possibility of contamination in the present case. However, a positive association would not conclusively establish the role of the family environment as a mediating factor.

One set of mothers was given a shortened form of the EFT and a figure-drawing test approximately 2 to 3 years after their initial interview. The testing took place in the home situation under less-than-ideal conditions. Despite this shortcoming, the EFT and sophistication of body concept were significantly correlated in the sample of mothers.¹⁴ Further, these scores related significantly to the interview classification of mothers as "facilitators or inhibitors of differentiation" in their children. EFT scores did not relate significantly to the interview data, however. The sophistication-scale scores taken from the mothers' figure drawings were also significantly correlated with the various criteria of analytic functioning in the sons. On the other hand, the corresponding correlations for mothers' EFT scores did not achieve statistical significance. Witkin et al. (1962) attribute the low predictive value of the mothers' EFT

performances to the difficulties in test administration. Conceivably, the EFT might be tapping a factor other than mode of field approach when administered under the special conditions that exist in the home. In sum, the hypothesis that the mother's mode of field approach will correspond to that of her son received only partial support. Regrettably, one cannot tell whether the cognitive similarity between mother and son is, in fact, quite weak or whether the link is really quite strong but vitiated by the special assessment conditions that prevailed in Witkin's research.

A fundamental question left unanswered by the work of the Witkin group on parent-child antecedents concerns the role of the father in fostering or inhibiting "differentiation" in the child. Recall further that Witkin's research into the possible family origins of an analytic versus a global field approach has been based exclusively upon boys. Corah (1965) has attempted to fill in the gaps by examining the field-dependence levels of both mothers and fathers in relation to the field-dependence levels of both sons and daughters. Corah selected 30 boys and 30 girls (ranging in age from 8 to 11) from 60 middle-class families. The EFT and figure-drawing procedures were used to assess field dependence in both parents and children. The CEFT (Karp and Konstadt, 1963) rather than the standard EFT was administered to the children. Age and IQ were regressed out of the field-independence indices before the parent-child correlations were computed. The correlational pattern when EFT, or CEFT, and figure drawing were combined into a single index assumed the cross-sex form (i.e., the field-dependence scores of mothers and sons and of fathers and daughters were positively and significantly associated). The same-sex correlations were nonsignificant.

The Corah results are clearly consistent with those reported in Witkin et al., but at the same time they introduce a new complicating element. Why the relation between parent and child in regard to the analytic-global dimension should assume the cross-sex form is not easily explained. Corah has proposed that it is the opposite-sexed parent who attempts to foster the appropriate sexual identification in the child. But independent evidence for such an assertion is lacking, and, furthermore, the theoretical link between an

¹⁴ Though it is correlated with EFT, one can question the use of figure drawing as an index of analytic functioning if the latter is to be conceptualized as the ability to overcome an embedding context.

"appropriate sexual identification" and field independence is not at all clear

Other relevant evidence can be brought to bear on the issue. Bieri (1960) explored the relation between field dependence, on the one hand, and parental identification and acceptance of authority, on the other, in a sample of college men and women. Field dependence was assessed by the EFT, parental identification was assessed by the degree of similarity of self-ratings to mother- and father-ratings on a semantic differential,¹⁵ acceptance of authority was assessed with the Bales-Couch AA scale, which has been shown by Bieri and Lobeck (1959) to correlate highly with the F scale (Adorno, Frenkel-Brunswick, Levinson, and Sanford, 1950).

The findings obtained by Bieri (1960) that are of particular interest concern the simultaneous effects of AA level and parental identification upon field dependence. For males, greater field independence occurred when low AA was combined with *mother* identification. Females, by contrast, manifested the highest level of field independence in the combined presence of low AA and *father* identification. Thus the cross-sex feature of Corah's (1965) results finds some parallel in the outcomes of Bieri's research. Bieri has, in addition, provided some insight into the psychological mechanisms that may mediate the cross-sex, parent-child associations in the domain of field dependence-independence. At the same time, caution should be exercised in interpreting Bieri's results, given the exceedingly small *N*s that result when AA and identification variables are treated simultaneously.

In the research described thus far, the large majority of subjects had both parents in the home during the formative years. What would be the effect of the father's absence from the home on level of field dependence? This question was explored in a study conducted by Barclay and Cusumano (1967). These authors proposed that father absence would have a differential effect on the son's overt as opposed to covert masculine identification. It was expected that the boy's sex-role con-

flict produced by growing up in an exclusively matriarchal setting would lead to a compulsive denial of feminine tendencies, with the resultant consequence of no difference between father-absent and father-present boys in extent of overt masculine identification. This expectation was confirmed in a sample of 40 adolescents (with a mean age of 15) divided into 20 father-absent and 20 father-present boys matched on age, grade point average, IQ, and socioeconomic status. In the father-absent group, no real or surrogate father had lived in the subjects' homes after the boys had achieved 5 years of age. No significant differences emerged between the groups on the Gough (1957) Femininity Scale from the *California Psychological Inventory*. Similarly, no significant differences were observed on a semantic differential requiring ratings of self, father, and mother. In sum, extent of overt masculine identification was no less in father-absent than in father-present boys.

The second hypothesis formulated by Barclay and Cusumano asserted that father-absent boys, in contrast to father-present boys, would reveal their sex-role conflicts at a deeper, more basic level in the form of a passive, field-dependent orientation. The RFT was administered to all of the adolescents participating in the study. Comparison of the RFT performance of the father-absent and father-present boys indicated a significantly higher level of field dependence in the father-absent group. It should be further noted that both groups were equally divided into white and Negro adolescents, with Negroes yielding higher levels of field-dependence than whites. Race did not interact significantly with the variable of father presence versus absence.

In sum, the data are highly consistent with the Barclay-Cusumano hypotheses. There is somewhat more incongruity, however, between the outcomes of the Barclay-Cusumano research and the results of studies considered earlier. It will be recalled that the cross-sex identification of the son with the mother under certain conditions was associated with greater field independence. Recall further that field-dependence levels of sons were correlated with those of their mothers, not their fathers. Now, we observe that the absence of the father from the home does have a significantly depressing effect on a male child. It is, of

¹⁵ It is rather doubtful that such an assessment gets at the essence of the identification concept. Nothing more is implied in the present context than perceived similarity to a parent.

course, also possible that the results can be attributed to the altered character of the mother role in the father's absence. Conceivably, the mother is forced to play a more harshly authoritarian role in the father's absence, a factor which might inhibit the growth of an analytic or a field-independent style in the child. Of great relevance in this regard is the Witkin et al. (1962) evidence indicating that mothers classified as "inhibiting differentiation" claimed that their husbands did not participate in decisions about their sons' raising. Such evidence is also consistent with Seder's (1957) observation that fathers were more likely to be the disciplinarians for field-independent boys, whereas mothers filled the disciplinary role for field-dependent boys.

It is difficult to comprehend why Barclay and Cusumano did not report the correlations between their overt and covert indices. These could be very helpful in understanding the processes at work. For example, did the boys with the greatest hypermasculinity at the level of overt identification also yield the highest levels of field independence? In other words, are the relationships across the covert and overt indices positive, negative, or random? Were the relationships similar or different for the father-present and father-absent groups? Such important questions remain unanswered in the Barclay-Cusumano report.

It is now apparent that the issue of sex differences is closely intertwined with the problem of parent-child antecedents of field-dependent behavior. In the section that follows we shall confront the matter of sex differences directly.

Sex Differences There now exist several dozen studies which have reported that males perform better than females on the EFT, RFT, and BAT measures of field independence. The relevant studies are cited in Maccoby (1966). The greater field independence of males, though generally achieving statistical significance, is of relatively small magnitude. Within-sex variation in field dependence is very substantial. The consistent small difference observed between males and females has become something of a *cause célèbre* in the personality-cognition area, as various genetic, physiological, learning, and cultural factors have been advanced to account for the apparent sexual inequality. We shall con-

sider these diverse interpretations in due course.

To begin on a cautionary note, it should be stressed that sex differences in field dependence have not been observed in children in the 4 to 8 age range (Goodenough and Eagle, 1963; Maccoby et al., 1965), nor have sex differences been obtained in geriatric groups (Schwartz and Karp, 1967). Occasionally, sex differences have not been obtained in college samples (e.g., Bieri, 1960). Differential sex selectivity—the greater percentage of eligible boys than girls who go on to higher education—would tend to operate against the emergence of a sex difference at the college level. Girls who enter a college or university may be considerably more field independent than their peers who settle for a high school diploma. Thus sex differences are likely to be most pronounced between the upper elementary school grades and the last year of high school. It might be noted that these are the years when sex-role differentiation shows a pronounced increase.

In an effort to reduce within-sex relative to between-sex variance in field-dependence scores, certain investigators have gone beyond the simple, biological sex distinction to an examination of sex-role identification. The availability of masculinity-femininity scales (e.g., Gough, 1957) has naturally fostered this trend. Regrettably, little relevant research has been carried out on samples of children. The most definitive study (Vaught, 1965) is based on college students. Vaught examined RFT performance in males and females as a function of sex-role identification (assessed with Gough, 1952, femininity scale) and ego strength (assessed with the Barron, 1953, ego-strength scale). Vaught hypothesized that the presence of high ego strength—a dimension closely linked to self-esteem—would tend to reinforce associations between masculinity and field independence and between femininity and field dependence.

Although significant main effects were obtained favoring males over females, masculine identifiers over feminine identifiers, and high ego-strength subjects over low ego-strength subjects in level of field independence, the significant triple interaction among these three components is the finding of major interest. For males, low ego strength was as-

sociated with field dependence, high ego strength with field independence, regardless of sex-role identification. For females, in contrast, high ego strength was associated with field independence in the presence of low or medium feminine identification, but high ego strength combined with high femininity yielded extremely high field-dependence levels.

Vaught bases his interpretation of his findings on Sarbin and Jones' (1955) contention that ego strength reflects role-taking ability. Feminine males and masculine females are presumed to represent unstable role identities, with the consequence that ego strength becomes the major determinant of mode of field approach. Where biological sex and sex-role identification are consistent, on the other hand, ego strength is presumed to be of lesser importance in regard to field dependence.

It is of interest to compare Vaught's findings with Bieri's (1960) evidence on cross-sex identification with parents in relation to field dependence. The findings are reasonably consistent for female subjects if one can assume that a masculine identification and high ego strength are in some way equivalent to identification with the father and a less authoritarian outlook.¹⁶ Those are the conditions in the respective studies that are associated with field independence in females. The consistency is somewhat less pronounced for male subjects, however. It will be recalled that Bieri found the highest levels of field independence in mother identifiers with a nonauthoritarian orientation. Vaught obtained relatively high field-independence levels in high-femininity males with high ego strength, but the low-femininity males were somewhat more field independent overall. On the whole, the correspondences between the studies are encouraging, for neither sex-role and parental identification, on the one hand, nor ego strength and nonauthoritarianism, on the other, can be treated as equivalents. The fundamental point demonstrated by both the

Bieri and the Vaught studies is that a good part of the variance in field dependence left unexplained by biological sex differences can be accounted for on the basis of psychological variables relevant to sex role. The evidence that cross-sex-typing contributes to field independence in females is quite strong. There is greater ambiguity regarding the advantage of cross-sex-typing for males on field independence, although data can be found in support of such an inference.

The foregoing discussion of sex differences has been based on the presumption that statistically significant differences between the sexes on EFT and RFT, for example, necessarily imply that boys are, indeed, more field independent and analytic, whereas girls are more field dependent and global. In a provocative paper, Sherman (1967) has seriously questioned whether such implications can in fact be drawn. Her argument, in brief, runs as follows: There is considerable evidence to suggest that the RFT and EFT (or the highly similar Gottschaldt figures) are significantly correlated with tests of spatial ability (Gardner, Jackson, and Messick, 1960; Podell and Phillips, 1959; L. L. Thurstone, 1944). Females have been shown to perform more poorly than males on spatial tasks even when there is no embedding context to be overcome. Reviews of this literature are available in Anastasi (1958) and L. E. Tyler (1965). Males are better than females in the spatial area because cultural sex-typing provides the male with more opportunities to practice spatial tasks. With adequate training, girls' spatial ability could be improved, with consequent declines in alleged field dependence and globality. That is the sum and substance of Sherman's case. She offers a strong argument for sex-typed learning as the basis for the observed sex differences.

Sherman's paper is important and hence deserves additional, more critical consideration. It is difficult to dispute the point that spatial ability may be contaminating the measures of analytic-global functioning. If spatial tasks without properties of embeddedness are, nevertheless, substantially correlated with Witkin's dimension, it is impossible to invoke the argument that an analytic style produces a higher level of spatial ability. It will be recalled that the Witkin group, with some

¹⁶ The link between ego strength and low authoritarianism finds strong support in the research of Jensen (1957), who has found that "prejudiced, authoritarian persons have less well-developed ego defenses and thus are more exposed and vulnerable to psychological stress." (p. 310)

justification, claimed that an analytic style was responsible for superior performance on WISC subtests highly loaded on the analytic factor. Recent research, in line with Zigler's (1963a, 1963b) criticisms, has controlled for IQ when relating field-dependence indices to other measures (e.g., Barclay and Cusumano, 1967, Crandall and Sinkeldam, 1964). Sherman's observations raise the issue of the possible value of statistically removing the spatial component from the field-dependence measures when they are related to other variables. It would be of great value to know whether the dimension of analytic versus global field approach is inextricably tied to a configural or spatial task format. If the statistical removal of the spatial element should serve to eliminate theoretically anticipated relations between field dependence and other variables, it would be most difficult to defend the overcoming of an embedding context as the critical aspect of the construct at issue. As we previously noted, performance on the criterion measures of field dependence bore no relation to performance on a verbal task with the properties of embeddedness. Hence it has already been demonstrated that the capacity to cope with an embedding context is not a *sine qua non* for analytic functioning as defined by Witkin and his associates.

Consider next the differential-practice argument to account for the female's inferiority in the spatial domain. To quote Sherman (1967) "Boys as a group spend more time in aiming activities and games, model construction, building with blocks and later with other materials. It seems very likely that these activities are involved in the development of spatial skills" (pp. 295-296). Maccoby has challenged such an explanation on the grounds that there is no evidence for it. The following quote from Maccoby (1966) is particularly instructive:

It is true that if one watches nursery school children at play, one is more likely to find boys building with blocks and girls placing doll furniture in a doll house or pretending to cook with beaters and bowls, but it is difficult to see why one of these kinds of object manipulation should lead to greater spatial ability than the other. We know little about what kinds of learning experiences are involved when a child dissects stimuli (as the analyt-

ical, field-independent child does) instead of responding to them globally, but it is difficult to see why sheer quantity of stimulus exposure should make a difference beyond a certain point (pp. 41-42).

In defense of Sherman, it should be noted that sex differences in field dependence are not evident at nursery school age, but rather emerge in the middle years of elementary school. It is not inconceivable that sex-typed activities assume a more spatial character for boys than for girls over time. As Sherman has noted, girls tend not to gravitate toward shop work, car tinkering, model building, and map reading. It is doubtful whether feminine-oriented tasks exist which call upon spatial skills to the same extent, but once again we are in the realm of conjecture.

The most dissonant evidence with respect to the hypothesis of masculine sex-typing of spatial activities derives from a study by Ferguson and Maccoby (1966) on the interpersonal correlates of differential abilities. From a large population of fifth-grade children, these authors selected a sample of boys and girls who showed marked discrepancies among verbal, number, and space abilities on the T. G. Thurstone (1958) Primary Mental Abilities Test. The interpersonal characteristics of these children were assessed by self-report questionnaires and peer ratings. Of special interest in the context of the present discussion is the personality of the boys and girls high in spatial ability but relatively low in number and verbal ability. Such differential spatial ability was associated with cross-sex-typing in both boys and girls. For boys with relatively high spatial relative to verbal ability, the peer ratings pointed to a behavior pattern of low aggression, low masculinity, and low mastery, and a high level of withdrawal. Consonant with the low masculinity ratings was the self-report evidence indicating a low score on the Sex-Role Acceptance Scale. Girls high in spatial ability, in contrast to the boys, scored higher in overt aggressiveness (peer ratings) and were less anxious about expressing aggression (self-report data). These findings are clearly paradoxical. If high spatial ability is a reflection of distinctly masculine sex-typed activities, it is difficult to comprehend why the boys judged least masculine should have the highest scores on spatial ability, while at the

same time the high space girls manifest much masculine-oriented behavior. Such outcomes cannot easily be reconciled with Sherman's differential-practice hypothesis, at least as far as boys are concerned.

It will be recalled that some evidence was found to support the idea that identification with the mother might enhance field independence in males (Bieri, 1960). But such processes of identification in college-age men seem quite far removed from the patterns of overt behavior manifested by the preadolescent boys with differentially high spatial ability in the Ferguson-Maccoby investigation. One clue to the puzzle is that the characteristics of the child high in spatial ability may be as much a function of his deficits as of his strength. The high-space children were simultaneously low in number and verbal ability. Conceivably, children who perform well on the EFT and the RFT have high number and/or verbal ability as well as strong spatial capacity. If this could be demonstrated, one would be forced to conclude that an analytic field approach involves more than simple spatial ability.

The most relevant evidence is presented by Bieri, Bradburn, and Galinsky (1958) who obtained substantial and significant correlations between EFT performance and mathematical ability (SAT-M) in college men and women. If such a correlation should also be present in children, it would necessarily have been eliminated in the Ferguson-Maccoby study by virtue of the manner in which the children in their sample were selected. Of considerable interest in this regard is the evidence that boys with differentially high number ability received high masculinity ratings from their peers. To the degree, then, that numerical ability is separated from spatial ability by differential selection procedures, the latter may simply not manifest the kind of close link to Witkin's analytic-global dimension proposed by Sherman (1967).

Another point of contrast between spatial ability and analytic functioning in the Witkin sense can be noted in the sociometric findings of the Iscoe and Carden (1961) study. Among sixth-grade boys, those scoring the highest on the EFT measure of field independence were the most frequently chosen by their peers on affective and work criteria. Ferguson and Maccoby, it will be recalled,

found that their high space boys were low in masculinity and high in social withdrawal. These are hardly the characteristics likely to contribute to a preadolescent male's popularity and influence with his peers. Where sixth-grade girls are concerned, Iscoe and Carden observed a significant sociometric preference for those with a global field approach. Thus, for girls, the data on field dependence and spatial ability are in agreement. Whether a girl is high in field independence or in spatial ability, she is likely to manifest more masculine qualities, and this inappropriate sex-role behavior might be expected to reduce her popularity and influence with same-sexed peers. Iscoe and Carden also found that anxiety level was unrelated to EFT performance in boys, but field-independent girls relative to their field-dependent peers expressed more anxiety symptoms on the Children's Manifest Anxiety Scale (Castaneda, McCandless, and Palermo, 1956). The causal direction of this relation cannot be definitely established, but a reasonable conjecture is that the unpopularity of the more masculine, field-independent girls contributes to the symptoms reflected in the CMAS.

To continue the comparison of spatial and analytical ability, consider the matter of training. The evidence on this point with regard to an analytic field approach has been largely negative (e.g., Elliott and McMichael, 1963; Wolf, 1965). In contrast, spatial visualization has been shown to improve during engineering study (Blade and Watson, 1955) and by means of programmed instructional techniques (Brinkmann, 1966). Such efforts have been quite intensive and prolonged, and their success raises the issue of whether the training failures in analytic, field-independent functioning might have been due to the brevity or inadequacy of the training procedures employed. It would be of interest to observe whether intensive training in spatial visualization would enhance field independence on Witkin's three criterion tasks. Such an outcome would serve to reinforce the view that the spatial component is a critical aspect of Witkin's dimension.

Cross-Cultural Findings. Within the past few years, data relevant to the field-dependence dimension have been collected in a number of primitive non-Western cultures. Witkin (1967) has recently reviewed this

cross-cultural evidence. Its importance can hardly be exaggerated, given claims by Witkin and others that certain kinds of family influences and cultural sex-role differences contribute to greater or lesser field dependence. Primitive societies with diverse child-rearing practices and norms of sex-typed behavior constitute a "natural laboratory" for tests of some of Witkin's major hypotheses.

Consider first the research of Dawson (1967a, 1967b) in Sierra Leone (West Africa). As Dawson (1967a) has pointed out, the tribal social organization and child-rearing methods in Sierra Leone "place considerable emphasis on values of conformity, group reliance, maintenance of authority, polygamy and strict discipline" (p. 116). Such values should, in line with Witkin's hypothesis, contribute to high levels of field dependence. Dawson describes the way in which Temne children in Sierra Leone who resist their elders' wishes are accused of being "affected by witchcraft" and are accordingly punished. An additional feature of the Sierra Leone cultural scene is the polygamous family group, which forces the mother to assume a dominant role in raising her children. The adequacy of the father as a role model for the son is limited, given the responsibilities of the father toward other wives and children.

Within the overall pattern of parent-child relations in Sierra Leone, further variations can be distinguished. Thus parents can be expected to show some variation in disciplinary strictness. Dawson (1967a) had his subjects (male skilled workers aged 20-24) rate their mothers and fathers as "very strict," "fairly strict," or "not so strict." These categories of strictness were significantly related to field dependence (assessed with the EFT and Kohs Blocks) for mothers but not for fathers. Thus, consistent with Witkin's hypothesis, those males who felt that they had been subjected to very strict discipline by their mothers (implying a pattern of maternal dominance) were more likely to have higher field-dependence scores.

Further corroborating data for the influence of maternal dominance on field dependence come from a comparison of subjects drawn from the Temne and Mende tribes in Sierra Leone (Dawson, 1967a). In contrast to the Temne mother, for whom extreme dominance and strictness is the norm, the Mende mother

is considerably less dominating and more permissive and encouraging of individual initiative in her child. Consistent with expectations, a comparison of young adult males from the Temne and Mende tribes revealed the Temnes to be significantly more field dependent than the Mendes on the EFT. These results clearly strengthen the proposition that field independence in the son will be inhibited or facilitated as a function of the degree to which his mother encourages individual initiative and independence.

In a subsequent paper, Dawson (1967b) factorially analyzed the data from his Sierra Leone samples. Of particular interest in the present context is a powerful factor with positive loadings (in the field-independent direction) for EFT, Kohs Blocks, three-dimensional perception of pictures, general intelligence, and educational achievement. Maternal dominance and preference for traditional (as opposed to Western) values yielded substantial negative loadings. The relatively high loadings for intelligence and education are disturbing, and one must regret that these variables were not held constant or regressed out of the field-dependence scores when relations with child-rearing variables were examined.

The variable "three-dimensional perception of pictures" refers to the capacity to attribute depth when viewing two-dimensional pictures. Hudson (1960) reported that many Africans lacked this capacity, possibly as a consequence of lack of exposure to pictorial materials. Dawson included Hudson's materials in his research. These materials consist of a set of pictures containing various objects, where the subjects' task was specifying which of a number of objects was closer in distance to another object. The relation between performance on this test and on the EFT again highlights the role of spatial factors in regard to the field-dependence dimension.

We turn now to a cross-cultural comparison of field dependence in the Temne from Sierra Leone and the Canadian Eskimo (Berry, 1966). The Eskimo offer a sharp contrast to the Temne on a number of ecological and cultural variables. The Temne exist in a physical environment characterized by a diversity of vegetation of variegated color. Farming constitutes the main occupation, hence there is little need to stray from the fixed paths through the bush. By contrast, the

Eskimo inhabit a bleak environment distinguished by minimal variation in color. Given an environment of fairly uniform visual stimulation and a dependence on hunting for subsistence, the Eskimo must, in order to survive, develop certain perceptual skills. They must learn to discriminate very slight variations in their physical environment, and they must develop an articulated view of open space so that they can orient themselves relative to the objects around them. More geometric-spatial terms are available in Eskimo than in Temne language. Further, the Eskimo are noted for their soapstone sculpture, their graphics, and their map-making skills, activities that are quite alien to the Temne. The figure drawings made by Eskimo children actually appear to be more articulated than those produced by a comparison group of American children (Harris, 1963).

The difference in socialization practices between the Temne and the Eskimo is particularly striking. We have already discussed the strong emphasis on severity of discipline and conformity pressures in the case of the Temne. Children in the Eskimo culture, on the other hand, are generally the recipients of unconditional love and approval, are rarely punished (even verbally), and are able to manipulate parents into granting their wishes. The child is encouraged fairly early in life to assume responsibility for his welfare. Given these striking differences between child-rearing practices in the two cultures—differences that appear relevant to Witkin's conceptualization of the forces inhibiting or facilitating differentiation—Berry (1966) predicted higher field-dependence levels in Temne subjects and lower field-dependence levels in Eskimo subjects.

For both the Temne and Eskimo, Berry selected samples living in relatively isolated rural areas (the "traditional" group) and samples living in more urban, Western-type environments (the "transitional" group). Males and females were sampled equally from all four groups. In addition, Berry sampled equally from five age groups: 10 to 15, 16 to 20, 21 to 30, 31 to 40, and over 40. Within the traditional and transitional categories, the Temne and the Eskimo had comparable levels of formal education. For control purposes, two Scottish samples, comprised largely of farmers and manual workers, were also se-

lected for study. Consistent with the traditional-transitional comparison, one sample was drawn from a small farming village, the other from a city.

Four tests of a spatial character—EFT, Kohs Blocks, Morisby Shapes, and Raven Matrices—were administered to all subjects. Virtually all of the correlations between the four tests in the six samples were statistically significant and substantial. Sherman's (1967) assertions regarding the spatial aspects of Witkin's construct are clearly confirmed in Berry's work. Comparison of the Temne and Eskimo separately for "traditional" and "transitional" samples yielded highly significant differences on all four of the tests described. A great gulf was found between the Temne and the Eskimo, with hardly any overlap in scores between the two groups. The Eskimo clearly exceeded the Temne in field independence and spatial ability, furthermore, they came very close to matching the performance of the Scottish samples.

Although it is hardly surprising that the transitional Temne were more field independent than the traditional Temne, the fact of superior performance in transitional relative to traditional Eskimo is rather puzzling. The ecological requirement of highly articulated space should be considerably less marked for Eskimo who live on a trading post and engage in limited hunting than for those who live in small camps and rely entirely on hunting for a livelihood. The transitional Eskimo, of course, have had more formal education than their traditional counterparts, hence they may well have developed the test-taking attitudes that contribute to better performance. The need for a finely articulated perception of space in conducting one's livelihood obviously contributes to doing well on spatially oriented tests. Nevertheless, tests of any sort do require that the subject sit fairly still for an extended period of time, focusing his attention on the task at hand. Such experience is not entirely foreign to the westernized Eskimo with a few years of schooling. Also contributing to the observed difference between more rural and more urbanized groups, according to Witkin (1967), is the selective migration of relatively field-independent persons to populated areas. Note should be taken, finally, of Vernon's (1965) claim that Eskimo coming from the most isolated Arctic communities

performed better on spatial tests than those living in closer contact with whites. Obviously, more research is needed to resolve these discrepancies.

We turn, finally, to the matter of sex difference within the context of culturally prescribed sex-role-typing. Berry has pointed out the sharp contrasts between Temne and Eskimo societies in the way females are treated. Unlike the Temne, who exercise very firm control over wives and children, the Eskimo allow their women and children a considerable degree of autonomy. Consistent with these cultural differences, the Temne males were found to be significantly more field-independent than the Temne females on most of the tests employed. Comparable sex differences were observed in the Scottish groups, but no sex differences of any consequence were obtained from the Eskimo samples. This result was replicated in another sample of Eskimo by MacArthur (1967). In sum, the Berry and the MacArthur data constitute strong evidence for the proposition that sex differences in field dependence may be largely a function of social-role influences.

We conclude the present section with a brief consideration of the nature-nurture issue. The Eskimo have lived in the same environment over a long period of time in relative sexual isolation from other groups. Given the adaptive importance of an articulated mode of functioning in the harsh environment of the Eskimo, differential selection on that attribute may have taken place. No such adaptive selection was ever necessary in the highly articulated Temne environment. It is doubtful, however, whether such evolutionary interpretations will prove theoretically useful in the present context. Of much greater relevance is the evidence of strong associations among the ecological demands of a culture, socialization practices and their consequences for sex-role-typing, and the level of field dependence typical of the culture. On the whole, this cross-cultural evidence is quite congruent with the outcomes of American investigations concerned with the effects of parent-child interaction and sex-role identification upon level of field dependence. It appears that Witkin's twofold classification of mothers as either inhibiting or facilitating differentiation has its analogue at the level of primitive, homogeneous cultures.

It has been shown that field dependence in the Temne has as much adaptive, survival value as field independence in the Eskimo. Each mode of field approach fits the ecological requirements of the particular culture. What are the ecological requirements of the American culture? It is commonly assumed that there is wide heterogeneity in such requirements as a function of a host of demographic variables. Accordingly, can one justify a value bias in favor of field-independent functioning? No conclusive answer to the question is possible, of course, but we shall speculate about it a bit more in the process of a final summing-up of the contribution of Witkin, his co-workers, and other investigators whose work has been inspired by the Witkin group.

Evaluative Summary. To begin with the positive, there is no doubt that the Witkin team has uncovered and empirically exploited an exceedingly important dimension of perceptual-cognitive functioning. Its importance derives in large part from its fertility: the dimension is not confined to perception but impinges upon cognition, intelligence, personality, and social behavior. The boundaries between these various domains—so often treated in isolation from one another in psychology—are shown to be exceedingly permeable in Witkin's research. The analytic-global dimension, in Witkin's hands, has become a major organizing principle around which many aspects of the child's functioning have been shown to cluster. In other words, to describe a child as analytic or field independent as opposed to global or field dependent is to provide a huge amount of information about that child. The constructs developed by the Witkin group have considerable "surplus meaning."

On the negative side, issue can be taken with the decision of the Witkin group to use "differentiation" as their major unifying construct. Zigler (1963a, 1963b) has proposed that the dimension at issue might have been better labeled "spatial decontextualization," after Podell and Phillips (1959). Such a proposal has a great deal of merit, given the evidence that the field-articulation principle is manifested largely on spatial tasks. Certainly, there is nothing in the differentiation concept as formulated by Lewin or Werner to suggest that its field of applicability is

limited to the spatial domain. On the other hand, as we have noted, performance on Witkin's spatial tasks does relate to areas of personal functioning that have no relation whatever to spatial decontextualization. Some organizing principle was obviously needed to tie the diverse sets of variables together. The Witkin group chose the differentiation construct to serve this organizing function. Perhaps the link between the wide variety of processes examined and the construct of differentiation was largely metaphorical, as Zigler has claimed. Nevertheless, the preference for differentiation over spatial decontextualization may have some justification, given the limited generality of the latter construct. Still another term might have been superior, but there are as many disadvantages to coming up with new labels as there are in refurbishing old ones.

The controversy over the differentiation issue between Zigler and the Witkin group can probably be traced to the Witkin group's presumption that all processes relevant to differentiation can be incorporated within their definition of that term. Yet it must be admitted that processes with little or no relationship to Witkin's differentiation cluster are nevertheless subject to Weiner's orthogenetic principle. That principle, it will be recalled, simply states that development proceeds from a relatively global state to one of differentiation, articulation, and hierarchic integration. As stated, the principle is sufficiently general to accommodate verbal and numerical as well as spatial-analytic capacities. Thus the evidence that verbal-numerical processes are only weakly related to spatial-analytic ability in the work of Witkin and his associates cannot mean that verbal-numerical processes do not follow Weiner's main developmental principle. Rather, such findings must necessarily mean that the Witkin group has examined a particular form of differentiation, perhaps the most important and most highly generalized form, while choosing to ignore other forms.

Paradoxically enough, the data reported by Witkin and his co-workers are consistent with Weiner's views on multilineal development, for certain cognitive capacities obviously follow a different route than that taken by spatial decontextualization. One is hardly justified in attacking Witkin for choosing this route, given the enormous payoff in significant

findings that ensued. The alternative research strategy of pursuing all possible paths simultaneously is hardly viable.

The dispute over the differentiation issue appears to be partially semantic. On the one hand, differentiation was originally defined by Weiner as a heuristic principle that does not lend itself to experimental acceptance or refutation; its value lies in the network of constructs generated by it. For Witkin, on the other hand, differentiation has become an explanatory, higher-order construct capable of tying together a diverse set of lower-level dimensions. The point worth noting amidst all of the heated controversy is that the validity of Witkin's findings would not be diminished if their organizing principle were designated by a term other than differentiation. It is perhaps unfortunate that the Witkin group chose a term that implicates variegated meanings and levels of abstraction. But the ultimate value of Witkin's work will almost certainly rest on the significance of the further research it generates, rather than on the specific explanatory construct in favor at the present time.

Apart from its theoretical implications, Witkin's work is of practical import, particularly to those working in educational fields. There is a strong tendency for teachers in our elementary schools to value verbal and number skills. The Witkin team has pointed to another domain of intellectual functioning, likely to be ignored by the schools, which is nevertheless highly relevant to the child's modes of thinking, feeling, and acting. A recent paper (Witkin, Fateison, Goodenough, and Birnbaum, 1966) has shown some boys deemed mentally retarded to be nevertheless approximately average relative to their age group in field-articulation capabilities, a fact that might be put to valuable educational use. Also instructive is the high level of field independence in Eskimo with minimal levels of formal education. Recall that there were no material differences in field dependence between Eskimo and Scots, despite the educational opportunities open to the latter.

In sum, it would appear that formal schooling tends to develop verbal-numerical capacities, whereas the development of an articulated mode of field approach may be under the influence of early family experience. Witkin (1967) has proposed that programs for

the culturally disadvantaged have neglected the issue of the development of field independence and have instead focused on the enhancement of verbal skills. The paradoxical elements in the equation are the fact that cognitive capacities determined by early familial factors would be most difficult to modify, and, furthermore, the more disadvantaged children, on the basis of Witkin's evidence, already manifest the least deficit in the analytic area. Of course, the presence of particular cognitive strengths, as we have seen, does not imply that they will be recognized by the important educational agents in the child's life. Nevertheless, one is faced with the difficult choice of devising programs of educational value that capitalize upon the existent analytic strengths of the child or that attempt to overcome the more glaring deficiencies in the child's repertoire of cognitive skills.

It is in the foregoing problem that one confronts the basic value dilemma inherent in Witkin's system. Can one really claim that field independence from the point of view of ecological requirements and societal needs is more socially relevant and useful than field dependence? Solid evidence exists that field dependents are more alert to social stimuli. They do better than field independents, for example, in tasks that require the incidental memory of social words (Fitzgibbons, Goldberger, and Eagle, 1965) and the memory for faces (Messick and Damarin, 1964). Groups of field-dependent males are able to achieve a unanimous consensus in significantly less time than is required by field-independent groups (Wallach, Kogan, and Burt, 1967). Field dependents are probably more skilled at the art of interpersonal accommodation, field independents are better able to resist the influence of others. When one reflects upon the adaptive requirements of our heterogeneous American culture, it is far from evident that the field-independent orientation is best suited to the needs of the future. In situations where social groups are in conflict over means, goals, and values, a cognitive style that facilitates fine articulation and sensitivity to the social environment may be considerably more helpful than a cognitive style encouraging articulation of the self and of external physical space. Before one begins to train children for field independence, then, the value dilemma

described must clearly be spelled out, for the long-term adaptive significance of a field-articulated cognitive orientation has not been definitively established.

Ipsative Analysis of Cognitive Functioning

All of the research discussed in the present chapter thus far has concerned itself with the description and interpretation of *inter-individual* differences for various cognitive dimensions. Boverman (e.g., 1960a, 1960b) has favored the ipsative, *intraindividual* analysis of data, that is, individual differences derived from the relative status of different functions within people. Thus when a large battery of tests is administered to a sample of subjects, it is feasible to express a particular individual's score on each test as a deviation from his overall mean score across all of the tests. Such an analysis has the effect of removing something like the intellectual *g* factor from a set of test data. It is beyond the scope of the present chapter to discuss the relative psychometric merits of ipsative versus normative measurement procedures. Such a discussion is available elsewhere (Boverman, 1962, 1963; MacAndrew and Forgy, 1963; Ross, 1963). An obvious difficulty with an ipsative approach is the fact of noncomparability between Boverman's work and the bulk of the research carried out by others, despite the use of identical cognitive tasks. The fact remains, however, that Boverman's research is of considerable substantive interest, and since some of it is based on adolescents and children, the relevant portions cannot be omitted from any comprehensive account of cognitive styles in children.

A set of 30 tests—some more perceptual-motor, others more conceptual in nature—was administered to a sample of 103 pairs of male and female adolescent twins (Boverman, 1964). The use of twins does not appear to be of any particular significance. A factor analysis of the ipsatized scores yielded two bipolar factors. The first factor was defined positively by the three scores from the Stroop test—speed of reading color words, naming color hues, and reading incongruously colored words (interference)—and by speed of tapping a simple pattern on the L. L. Thurstone (1944) Two Hand Coordination Test. Loaded negatively on the factor were the Gottschaldt Test, the Kohs Blocks, and the

Primary Mental Abilities Space and Reasoning subtests Bioverman has labeled the factor "automatization," given the positive loadings for simple verbal and motoric tasks. The tests that load negatively on the factor are strongly suggestive of Witkin's field articulation dimension.

The second ipsative factor was defined by positive loadings on the Primary Mental Abilities subtests of Verbal Meaning, Word Fluency, and Reasoning. A variety of tapping tasks and telegraph key operations yielded negative loadings on the second factor. The contrast between the conceptual and the perceptual-motor is very distinctly drawn.

The two factors obtained in the adolescent sample were quite comparable to those derived from two adult samples. Thus the two-factor, bipolar pattern reported by Bioverman seems to reflect stable contrasts in styles of cognitive functioning. There are, however, ambiguities in the outcomes of Bioverman's investigations. Particularly astonishing is the evidence that the kinds of interference represented by the Stroop and the Gottschaldt have opposite effects on individual performance. Bioverman (1964) attempts to explain this paradoxical outcome in terms of the role of the conflicting cues in the two tasks. In the Stroop, the correct stimulus attribute (the color in which the color name is printed) is directly perceptible, and the subject must suppress the strong, overlearned habit of reading the color words. In hidden-figures tests of the Gottschaldt type, the correct stimulus element is not directly perceptible, but rather must be discovered and extracted from an embedding context. One must grant that the two tasks at issue do pose quite different problems for subjects, but it is, nevertheless, a surprise to find the tasks located at the opposite extremes of a bipolar factor.

The interpretation of Bioverman's automatization factor could be extended along motivational lines. If weak automatization is essentially Witkin's field-independence dimension, it is conceivable that this automatization factor is not a cognitive or motor deficit, but rather a reflection of the field-independent's lack of motivation to work hard at an uninteresting, repetitive task. We already know that field independence is associated with less conformity (e.g., Jackson, 1958; Linton, 1955; Linton and Graham, 1959; Rosner,

1957). Field independents may simply fail to take a repetitive motor task very seriously and hence not put forth their best effort. This interpretation is sheer conjecture, of course. Further research is quite clearly needed.

Bioverman (1964) has attempted to relate the automatization factor to life performance in the case of adult samples. Data were available on the occupations of both the subjects (males) and their fathers. These were converted to occupational levels by means of the Hollingshead (1957) scales. Strong automatizers had achieved higher occupational levels than weak automatizers, despite the absence of any difference in years of education and overall intelligence. Further, the strong automatizer's occupational level manifested a sharp rise relative to father's occupational level. No such increase was obtained for weak automatizers. Again, if weak automatizers are truly field independents, Bioverman's data stand in sharp contrast with other evidence pointing to a significant, positive link between field independence and achievement motivation (e.g., Crandall and Sinkeldam, 1964). However, one must not lose sight of the fact that comparisons between normatively and ipsatively designed studies are not entirely legitimate.

We conclude our coverage of Bioverman's work with a brief discussion of two additional pieces of research based on adolescents and children. In the first (Bioverman, Bioverman, Vogel, Palmer, and Klarber, 1964) the automatization style was related to adolescent physical development in a sample of 16-year-old male students. Seventeen body measurements were obtained. No overall height or weight differences between strong and weak automatizers were observed, but the strong automatizers did have significantly shorter necks and legs and significantly wider shoulders than did the weak automatizers. The former group also possessed more body hair and shaved more frequently than the latter group.

Bioverman and his associates explain the observed physical differences on the basis of the higher androgen levels in strong automatizers, the consequence of which is a more rapid rate of physical maturing. Furthermore, a higher androgen level is presumed to enhance resistance to muscular fatigue, thereby accounting for the superior performance of

the strong automatizers on repetitive motor tasks. Such a physiologically based interpretation stands in obvious contrast to the proposal advanced earlier to the effect that weak automatizers (field-independent individuals) are not concerned about doing well on a tedious motor task.

The attempt to explain cognitive functioning in terms of physiological maturity and androgen level can be considered a precursor of a subsequent effort (Broverman, Klaiber, Kobayashi, and Vogel, 1968) to account for sex differences in cognition on the basis of physiological, hormonal sex differences. A great deal of evidence is offered (some of it from the animal behavior literature) in support of the view that females do better on simple perceptual-motor tasks, whereas males exhibit superior performance on perceptual-restructuring tasks. In the words of Broverman et al. (1968), "We hypothesize that the sex differences in cognitive abilities are reflections of differences in relationships between adrenergic activating and cholinergic inhibitory neural processes, which, in turn, are sensitive to the gonadal steroid 'sex' hormones, androgens and estrogens" (p. 24). Performance on the two tasks at issue—perceptual-motor and perceptual-restructuring—can apparently be manipulated by pharmacological hormonal agents that affect the adrenergic-cholinergic neural balance.

An array of evidence from diverse sources is brought forth by Broverman and his co-workers in support of a physiological basis for sex differences in cognitive functioning. Indeed, one is mildly astonished at so massive an effort in the service of explicating sex differences that are, after all, quite small in magnitude. As we have already demonstrated, sex-role identity may account for as much, if not more, of the variance in analytic functioning than does biological sex as such. It is, of course, feasible that the neural and hormonal processes described by the Broverman group have a direct impact upon sex-typing. An examination of such a possibility might be highly informative.

It will be recalled that Broverman et al. (1964) associated strong automatization with physiological characteristics of maleness. In Broverman et al. (1968), the emphasis is placed on male superiority on perceptual-restructuring tasks and female superiority on

automatized tasks. The earlier study linked weak automatization (high capacity for perceptual-restructuring) with a slower rate of physiological maturation as reflected, for example, in less hirsuteness. One is reminded here of the Ferguson-Maccoby evidence discussed earlier of lower masculinity in boys of high spatial ability. There are distinct resemblances between the Ferguson-Maccoby method of subject selection and the ipsative approach favored by Broverman. Indeed the first can be considered an ipsative analysis based on extreme groups. It is surely no accident, then, that the outcomes in the two cases at issue are reasonably congruent and different from results obtained in studies using the traditional normative methods.

We turn, finally, to a study of automatization in fourth-grade male children by Blum and Broverman (1967). Automatization was assessed with a variant of the Stoop test (the strong pole) and with various perceptual-restructuring tests (the weak pole). Regrettably, it was merely assumed that the bipolar factor that had been observed in adolescents and adults would emerge in children. Though this might well be so, empirical verification would have been highly desirable. A significant correlation was obtained between the automatization variable and the tendency to persevere with the same response in a test derived from the concept of rigidity or intolerance for ambiguity. This latter test consisted of a set of cards in which a cat was slowly transformed into a dog, and vice versa. Strong automatizers generally persisted with their original verbal report beyond the point in the series where the weak automatizers had shifted. While acknowledging that their results might be suggestive of greater intolerance for ambiguity or rigidity in strong automatizers, Blum and Broverman derive little comfort from such a conclusion. They argue, in fact, that maintenance of an original response during stimulus change may be "evidence of cognitive flexibility, since the individual is then including new and diverse stimulus relations within his original concept" (p. 101). Such an argument is not at all persuasive and merely suggests the need to make the current evidence congruent with earlier results pointing to the adaptive value of strong automatization.

Broverman has maintained that the greater the extent to which routine tasks and activ-

ities are automatized, the more energy will be available for coping with tasks of a novel, concentration-demanding type. One can certainly question the usefulness of such an energetic conception in the domain of cognitive functioning. Given the inverse relation between strong automatization and field articulation in perceptual structuring, we can only note with amusement that Broverman and Witkin place high value upon distinctly different, if not opposed modes of cognitive functioning.

One firm conclusion can be drawn from the studies cited in the present section. Until investigators begin to analyze their data both normatively and ipsatively (a rather unlikely and not necessarily desirable event), Broverman's work will be exceedingly difficult to articulate with the mainstream of research on cognitive styles.

THE ROLE OF MOTIVES, STANDARDS, EXPECTANCIES, AND ANXIETY

The heart of this chapter has been a description of the dimensions that seem to be helpful in accounting for reliable variation in the interpretation, storage, and transformation of information. This task was the chapter's central mission. However, it is not altogether inappropriate to append a brief discussion of the dynamic forces that initiate and maintain cognitive effort. These forces include, at a most general level, motives, standards, expectancies and anxiety over possible failure.

Earlier generations, wedded closely to Hull, Freud, and the nineteenth-century mechanists, did not wish to conceive of any action or thought without its special antecedent cause. The concepts of drive and need or motive became psychology's translation for *force* and *cause*, respectively. Natural observations of infants and the technically more elegant neurophysiological data have recently forced the important acknowledgment that some psychological and biological systems have their own spontaneous activities whose production does not depend upon deprivation, altered homeostasis, or impingement of external stimulation. There are many aspects of cognitive processing that proceed without a special motive or drive. The infant spontaneously fixates a figure that moves or possesses high contour contrast. He may cry over a discrepancy from

an acquired schema. The infant does not want to behave in this manner, he does not need to do so, he does. Newly hatched ducklings follow the first moving object they see. There seems to be neither practical nor theoretical profit in postulating a motive to follow the imprinting object.

Similarly, the child learns much from his environment without any special motive force catalyzing this learning. The infant learns a schema for his mother's face, he learns to laugh at a clown, to pile blocks into tall piles and to knock them down. The appearance of these responses seems to proceed naturally, requiring only contiguity and attention to relevant events. But the postulation of special motives is required, or at least helpful, if we are to understand why a child learns selected academic and socialization rules—to multiply, to tell the truth, to parse a sentence. Each culture requires its children to acquire many intellectual skills that they might not otherwise master because they would not devote long periods of sustained attention to them. Special motives are catalytic in this enterprise, they create the conditions that facilitate the acquisition of these cognitive competences. Individual differences among children in rate of acquisition of these tasks are typically attributable to differences in the strength of these motives.

Motives

It is a truism to state that a child's attention to events will be enhanced if he is motivated to attend to the events. If the child recognizes that attention to and subsequent mastery of a task are prerequisites for attaining a desired goal, he is likely to make an effort at mastery. How does a goal—or class of goals—acquire desirability or value? There are probably several mechanisms. For expository convenience, we shall discuss these under the rubric of specific motivational states without implying a commitment to a particular theory of the acquisition and content of human motives.

Motive to Maintain Response-Appropriate Contexts. The infant and child are always behaving in the sense of issuing responses to the stimulus context that surrounds them. With time, classes of responses gradually become firmly and selectively attached to specific people, objects, and contexts. The infant or child is often distressed when he is in a

context in which he has no response to make. An anecdotal observation is helpful here. If a 2-year-old child is brought to a room containing a variety of toys, he typically plays with the toys with zeal and joy. However, when he has become satiated after 10, 30, or 60 minutes he often whines, "I want to go home." He has no more responses to issue in this context, and he is motivated toward that place in which he has developed a richer repertoire of behaviors. The child develops a motive to preserve familiar contexts and to maintain contact with stimulus situations for which he possesses adaptive and easily issued classes of behavior. Differences in the modal environments to which children are exposed will produce motives for different contexts. A 1-year-old child who has experienced continual contact with his mother has developed a set of reactions toward her. He will have a strong motive for her presence. He announces this motive by crying when she is gone for too long a time, by pulling on her apron, by dragging the lamp from the living room to the kitchen in order to draw the mother into interaction with him.

The 5-year-old has learned a set of responses to particularly favorite toys, to the permanent objects in his home, to other children or siblings. If we place him in a context that does not allow manifestation of these habitual responses and one in which he has no responses to make, he becomes apprehensive and, occasionally, extremely fearful. There is therefore a motive to maintain contact with contexts and objects to which the child has an available set of behaviors and, correlatively, a motive to avoid contexts to which the child has not learned an easy set of behaviors. The motive for maintaining contact with the familiar is congruent with J. P. Scott's (1967) suggestion that puppies develop in the first 12 weeks a motive to maintain contact with a familiar context. The puppy vocalizes in distress if removed from a familiar to an unfamiliar context and stops his distress vocalizations when he is placed back in the familiar locus. It appears that the infant mammal—puppy or human—develops schemata for and responses to the context in which it grows. Encounter with a highly discrepant context elicits distress as an automatic reaction. This principle may be one basis for a child's motive to maintain contact with familiar people and contexts.

Motive for Pleasant Sensations and Reduction of Pain. The infant and child, of course, are motivated to reduce pain, anxiety, and discomfort. They learn to desire contact with those objects and events that have served this purpose in the past. Thus the child's motive to maintain a close relation with the mother or her surrogate rests on two bases—her association with reduction of discomfort and the fact that she is a target object to which the child has developed a set of behaviors. The parent or parental surrogate becomes a valued object and leads the child to develop a more symbolic motive—the desire for signs of positive evaluation of the child.

Motive for Symbolic Signs of Positive Evaluation. When the child begins to acquire language at about 18 months of age, the ground is prepared for the emergence of a desire for symbolic signs of approval and positive evaluation from others. This motive rests on previous learning in which words or phrases that represented good or its synonyms were associated with hedonically pleasant goal states and the availability of the mother as a target for behavior. The child wishes to be regarded as good and interprets positive evaluation from others as a sign of his goodness. If parents and adults who are valued give positive evaluation for mastery of cognitive tasks, the child will be motivated for that mastery.

Motives Characterized by a Wish for Selected Behaviors in Other People (hostility and dominance). The earliest motives in the child are for external events that produce a change in the child's own experience. By 2 to 3 years of age, a new set of motives emerges whose goal is the perception of a particular state in another person. A hostile motive is defined as the desire to see another display signs of pain, worry, fear, or discomfort. The wish is for misfortune and discomfort to befall another, and the gratification is contained in perceiving and/or knowing of that event. If the child thought that attainment of good grades would make a rival peer unhappy, hostility toward that peer could promote motivation to master intellectual tasks. A child who grows up in a peer group milieu in which intellectual competence is valued is more likely to work at school tasks in the service of hostile motivation than one who lives in a peer milieu which places minimal value on intellectual competence.

The motive to dominate has similar roots. It can be defined as the wish to have another assume a submissive posture with respect to the child. During preadolescence, dominance becomes elaborated and gives birth to the motive for power. Motive for power is defined as the desire for signs that enable the child to believe that another will assume a passive, submissive posture in relation to him. The motive to dominate could facilitate cognitive performance if such competence allowed the child to dominate others.

At a general level, desires for recognition, approval, dominance, and power can be distinguished in children. The specific behavioral routes chosen to gratify these motives will depend on the instrumental habits taught by the child's rearing environment. Some environments teach that attainment of athletic skills will lead to power, others teach that intellectual competence will provide the same goal. The specific behaviors the child chooses to gratify his motives are obviously relativistic with respect to the values of the social context in which he spends his formative years.

Identification The child also develops a desire to maintain and increase his similarity to desired models. This motive is part of the process of identification. Briefly stated, the child perceives certain models in his environment that possess attributes that he would like to attain (dominance, interpersonal competence, receipt of affection from others), and he tries to increase his similarity to these models by adopting their attributes. If intellectual competence is one of the model's central attributes, the child will attempt to increase his mastery in order to increase his similarity to the desired model.

Unfortunately, there has not been systematic empirical research on the relation of the motives for hostility, dominance, approval, or identification to quality of mastery. The greater variability of cognitive performance among boys than girls as well as the consistently poorer relation between social class and level of cognitive performance in boys than girls may be due to the more varied motive spectrum for intellectual competence that exists for boys. A primary motive for girls' performance in school is the desire to maintain symbolic signs of approval from parents and teachers. Upper-middle-class parents are more likely to promote this value with their daughters

than are lower-middle-class parents. As a result, the girls' motivation is likely to covary highly with social class. Although the motive for symbolic signs of approval is operative for boys, motives for hostility, dominance, and identification are more clearly operative for boys than for girls, and these latter motivations do not vary so strongly with social class.

Standards

As implied earlier, a standard is a belief about the desirability and appropriateness of a particular class of cognitions and behaviors. Children attempt to develop and maintain a belief system about the self that is maximally congruent with those attributes they have learned to regard as good, whereas they renounce and avoid the possession of attributes that they regard as bad. The bases for the evaluation of good or bad are culturally derived and for the Western community include the beliefs that one is valued by others, that one is attractive to others, that one possesses the necessary instrumental skills and competence to deal with selected problems, that one possesses the attributes and skills that the primary reference group judges to be appropriate for the biological sex, that one is rational and coherent, that one is independent and responsible, and that one does not engage in behaviors or become preoccupied with thoughts that are prohibited by the primary reference group.

The establishment of stable beliefs about what one should be and about how the world should appear is a universal characteristic of human functioning. The Western middle-class child is convinced he should tell the truth, speak and think coherently, and behave in a way appropriate to his sex role. The learning of standards is not always a simple consequence of reward and punishment. Although most 9-year-old girls have not been punished for being unattractive, they have learned a standard about attractiveness that is relatively stable and well articulated, and they try to maximize their attractiveness. The details on how such standards are learned are not clear, but it is likely that sheer repetition of a standard by someone who adheres to it and whom the child respects and loves can lead to a belief in its validity. The standards learned during the first 10 years of life derive in large measure from those communications about behavior

ior and attributes that are most frequently presented to the child by his family and friends. Parents continually remind their son, "Don't cry, don't cry," several times a day, several days a week for most of the weeks of the year. This repetition eventually has a permanent impact on the child's evaluation of the act of crying. The most significant standards are summary statements about proper thinking, feeling, and behavior; they are the ego-ideal.

The present chapter is concerned with competence and cognitive skills. It seems reasonable to suggest that a standard of intellectual competence will be an important determinant of whether the child will be highly motivated to strive for intellectual mastery. The child is often willing to reveal these standards. For example, children 7 to 17 years of age were asked whether they wanted to read material containing information only a few people knew or information that many people knew. There was a clear increase in preference for the unknown as the child grew older (Teeter, Rouzer, and Rosen, 1964). Similarly, fourth-grade subjects are more likely than second graders to choose a difficult over an easy task. As R. W. White (1959) suggests, the child develops a standard that dictates a desire to seek optimal challenge and to improve cognitive skills. This dynamic is essential to the educational enterprise.

Expectancies

An expectancy is an anticipation of an event. The anticipation can be an image or a thought. Expectancies are probably among the first psychological structures to develop, and they are constantly guiding behavior. One of man's continuing tasks is to create expectancies for the future so that he can reduce uncertainty about events to come. As we shall see, a major cause of anxiety is uncertainty about events in the future—the absence of fixed expectancies about the actions of others, one's own actions, or the vicissitudes of the environment. There are four major classes of expectancies. The first includes anticipations of the behavior of others; these form the essential fabric of social interaction. A second class includes the reactions of inanimate objects. The child learns that a glass will break if he drops it, milk will spill if he tips the cup. A third, more subjective class deals with the

individual's anticipation of the products of his own behavior, whether he will succeed or fail at a task. As a child approaches his third year he becomes more acutely conscious of his ability to complete certain tasks or to solve problems. The child seeks to avoid the unpleasant feelings characterizing failure, so he approaches tasks when he expects to succeed and avoids tasks when he expects to fail. The balance of successes and failures at a particular task accumulates over time and gradually leads to the establishment of a relatively stable expectancy for varied classes of problems. A final set of expectancies includes anticipations of internal feelings—feelings of pleasure, anger, fear, or sadness. The 6-year-old child has learned that if he steals money from his parents he will feel bad. We assign the label anxiety or guilt to this feeling state.

Relation of Motives and Expectancies to Quality of Cognitive Performance

Motives and expectancies are intimately related to each other and to quality of cognitive performance in a complex way. The most important relation ties expectancy of success at an intellectual task with motivation to master that task. If expectancy of success remains low for a long period of time, motive strength should become weak. If expectancy of success is high, motive strength will increase. There are several studies that verify this idea (Irwin, 1953; Jessor and Read, 1957; MacCorquodale and Meehl, 1953). Some studies, however, have not found a positive relation between motive and expectancy. Rotter (1954) suggests that these constructs are independent. Atkinson (1957, 1964) argues for a negative relation between expectancy and value of outcome in intellectual tasks.

With other conditions equal, the child who has a high expectancy of success will perform better than one whose expectancy of success is low. It has been demonstrated (Rosenthal and Jacobson, 1968) that a child's IQ may rise when the teacher in his classroom is led to believe that the child is brighter than he is. This rise in IQ was probably mediated by an increase in the child's expectancy of success which, in turn, increased the quality of his performance on the intelligence test.

The Crandalls have shown positive correlations between expectancy of success, on the one hand, and motivation and quality of per-

formance on intellectual tests, on the other. For example, 20 boys and 20 girls aged 7 to 9 years were asked to state whether they could solve mazes and memory tasks of varying difficulty (i.e., they were asked to state their expectancy of success). The subjects were later observed in a free-play situation, in which observers coded how long the subjects played with intellectual games and puzzles. There was a positive relation, especially for boys, between high expectancy of success and frequency of approach to the intellectual materials (Crandall, Katkovsky, and Preston, 1962). A related study with 12- and 13-year-old children found a positive correlation, for both sexes, between high expectancy of success and persistence with difficult mathematical problems (Battle, 1965). This relation between expectancy and quality of performance can be manipulated experimentally. Some children were given a high expectancy of success by receiving encouraging remarks from the examiner while they were solving a task. Others were given no such encouragement. Those with high expectancy were more successful in reaching the correct solution of a difficult problem (B. B. Tyler, 1958).

In a series of studies by Crandall and her colleagues on samples ranging in size from 70 to 256 there was a consistent positive correlation between stated expectancy estimates of intellectual competence and quality of report card grades. When the expectancy was specific to the particular area in which the grades were obtained, the correlations were very high (in the 80s). When the expectancy estimates were given for general competence, or in an area different from that in which the grade was obtained, the correlations were lower in the 30s but always positive (V. C. Crandall, in press).

Covariation between stated expectancy and quality of performance has some permanence and is remarkably consistent across populations. Although some prefer to interpret these correlations as indicating that high expectancies cause better quality of performance, it is just as reasonable to conclude that high quality of performance leads to higher expectancies. The subject's expectancy derives partly from his subjective assessment of the quality of his performance. It is most likely that performance and expectancy are wedded continually, each influencing the other, with the si-

multaneous resolution of these two forces affecting motivation.

Girls' expectancy estimates are consistently lower than those of boys (V. C. Crandall, in press), despite equivalent IQ scores and equivalent experimental feedback. Why do boys state that they will do better on intellectual tasks than girls? There are several possibilities. Boys, in their daily lives, may have actually experienced more positive feedback than girls, or they may have *perceived* more positive feedback. More likely, however, they may feel they should state a higher expectancy for intellectual tasks, since intellectual competence is more appropriate for the male than the female sex role. The sex differences in expectancy seem to persist despite equivalent objective feedback over a year.

In an interesting analysis, the entire entering freshman class at Antioch College in 1963 ($N = 380$) was studied over four academic quarters. At the beginning of each academic quarter the students were asked to list each course they would be taking and the grade they expected to receive. The expected grades stated by the males were always higher than those stated by the females ($p < .01$). However, examination of the actual grades received revealed no sex differences. Moreover, the mean expectancy statements and mean grades remained generally constant over the four quarters. Both males and females overestimated the grades they thought they would obtain, but males' overestimates were larger than those of females. Actual success or failure seems, in the short run, to be relatively unimportant in controlling expectancy statements. The subjects who, in actuality, were doing more poorly in school gave slightly inflated expectancy estimates. Among subjects who were in the middle of a group in actual ability (and therefore had ambiguous feedback), the boys gave slight overestimates, whereas the girls gave slight underestimates.

Crandall has also considered a variable dealing with the child's attribution of responsibility for the quality of his performance. By a questionnaire procedure, the child is asked whether he attributes his good or poor grades to his own efforts or to the vicissitudes of the external environment. Does the child take responsibility for his success and failure, or does he assign this responsibility to chance or actions of the environment? In general, chil-

dren who obtain better grades and have higher expectancies of success state that they are responsible for both success and failure, children with lower grades and lower expectancies of success attribute the cause of their evaluation to the environment (McGhee and Crandall, 1968). Moreover, there is some suggestion that sons with nurturant mothers are more likely to assume responsibility for their own success or failure than are sons with less nurturant mothers. On the other hand, daughters with nurturant fathers are likely to project responsibility more than are daughters with less nurturant fathers (Katzovsky, Crandall, and Good, 1967).

The relation between motivation to master a task and expectancy of failure is established early in development and can be seen in clear form as early as 2 years of age. Two-year-old children can become very involved in perceptual discrimination tasks. If the initial problems are easy and correct solutions come after a brief expenditure of effort, motivation is maintained and expressions of delight punctuate the child's performance. But after one or two failures there is a sudden, sullen withdrawal, which is difficult to overcome. Children seem to know when they have failed without being told, they know whether answers are correct or incorrect. The child prefers to avoid the pain of possible failure rather than risk the possible joy of success.

It is difficult to explain why expectancy of failure is so strong a force in governing the Western child's behavior. It is not likely that the visceral afferent feedback associated with failure is stronger or more salient than the feelings linked with success. When the child succeeds, he often smiles or laughs and munches his candy reward with gusto. The mosaic of stimulus experience linked with success seems to be as rich in sensory qualities as that accompanying failure. A second possibility is that the anticipation of the unpleasant feelings associated with failure is readily conditioned to a withdrawal response, whereas the anticipation of pleasant stimulation is less easily linked to the act of persistence. An escape habit seems to be more readily acquired than an approach habit. A third interpretation is that the related responses of inhibition and withdrawal are more easily elicited than the more diffuse acts that characterize involvement. Expectancy of failure often

leads to withdrawal, and it may take less incentive to elicit and maintain withdrawal than it does to maintain continued attention and involvement. This hypothesis is closely related to a final possible interpretation to which we feel most friendly. Failure leaves the child with no response to make to the task. The child who has failed is uncertain as to what he should do, so he withdraws. The child feels pressure to behave, but he has no response to make. The habits he has relied on are not appropriate, and he has no others available. If the child has no response to initiate, he will withdraw to a context where he does have an available response. This particular interpretation of the reaction to failure places the burden of the explanation as much on the availability of task-related responses as on the unpleasant-feeling tone of failure or disapproval. In any case, the Western child is driven to avoid failure, and the quality of his performance on any cognitive task is continually influenced by his expectancy of failure.

Anxiety

Anxiety is a label used to designate a class of unpleasant affective states. The reasons for the unpleasantness, which is usually accompanied by particular cognitions, are not easily specified. There is no sharply felt pain, nor does headache or muscle tightness universally accompany this feeling, and there is no fixed set of afferent sensations that characterize anxiety. At times, however, the person perceives a change in afferent stimulation which may result from discharge of the gastrointestinal tract or increases in heart rate, palmar sweating, shivering, flushing, or muscular contractions. The second central characteristic of anxiety is uncertainty about an unwanted event. Thus anxiety is usually defined as "an unpleasant feeling state accompanied by an uncertainty surrounding an undesirable event"¹⁷. To be sure, people sometimes mislabel the source of their feelings. The 8-year-old who is afraid of going to school and feels unpleasant

¹⁷ We do not wish to reify the construct of anxiety. Sarbin (1968) has cogently argued that anxiety was originally invented as a metaphor and, with time, became a myth. He suggests that the phrase "cognitive strain" be used to denote the experience that "arises in connection with solving problems of choice, conflict, interference, interruption, overloading, etc." (p. 418).

because he anticipates failure on an arithmetic test may tell his mother he is sick. He is not lying, he interprets his distress as illness and asks to stay home. Adults currently are often subject to the opposite error. The mass media have so sensitized them to the likelihood that many uncomfortable feelings are psychologically based, they may mislabel the ache of a viral infection as anxiety and take tranquilizers rather than a more appropriate drug.

We consider next the psychologically important relation between expectancy of success (or failure) in a particular problem situation and the experience of anxiety. This relation appears to be curvilinear. A child with low expectancy of success on a particular task is as certain of the outcome as is one who has high expectancy of success. Children at either of these extremes are assumed to experience less anxiety than children who are uncertain of their competence, that is, those who have a moderate expectancy of success or failure.

There is a small set of conflicts and sources of anxiety, in addition to anxiety over failure, that can block quality of cognitive performance. This set includes lack of congruence with sex-role standards, anxiety over competitiveness, anxiety over peer rejection, and anxiety over passivity. Let us consider each briefly.

Lack of Congruence with Sex-Role Standards. As indicated earlier, one of the child's major motives is to adopt behaviors and values that are maximally congruent with sex-role standards. Classification of an activity as masculine or feminine is based on the gender of the person most often associated with it. Schoolwork is usually classified as feminine, because women are normally associated with the monitoring of elementary school activity. Research has shown that girls and boys in the elementary school tend to classify school and school-related objects as more feminine than masculine (Kagan, 1964). The greater number of boys than girls with reading problems in the United States can be attributed, in part, to the fact that boys see the school situation as feminine and therefore not congruent with their sex. This conclusion is supported by the fact that on the island of Hokkaido in Japan, where men do much of the teaching in the elementary grades, there are no more boys than girls with reading problems (K. Miyake, personal communication).

The Role of Anxiety over Hostility. Since the public school classroom often contains a competitive, rank-order atmosphere, children who feel anxiety about outdoing a rival or feel guilt over the hostile motives that are associated with competitive mastery may begin to inhibit effort. It is possible that the girls' lower expectancy of success (V. C. Crandall, 1968) may be due to reluctance to report high estimates of performance, because they may be seen as "boasting" and, by inference, as aggressive and assertive acts.

Anxiety over Peer Rejection. One of the child's major motives is to recruit and maintain peer acceptance. He will inhibit many behaviors that the peer group regards as undesirable. Coleman's (1961) study of adolescent society indicates that children's performance in school tends to be in close accord with the values of the peer group. Thus strong desires for peer acceptance and anxiety over peer rejection can inhibit involvement in the school situation.

Anxiety over Passivity. A final source of conflict, especially relevant in the early school years, concerns the child's anxiety over playing the passive role. Typically, the child is placed in such a passive position in the school situation. He is to sit quietly, listen to the teacher, and conform to her requests. Some children have a conflict over passive submission to adults and are threatened by such a posture. If the anxiety generated by this conflict were high, it could lead to poor performance in the school situation. Boys usually have greater anxiety over passivity than girls, and this may be one more reason why boys' performance in the elementary school years is usually inferior to that of girls.

EPILOGUE

Few systematic conclusions flow easily from this long, yet not exhaustive review. Inquiry into variation in cognitive functioning has not had the beneficial guidance of strong theory and, on occasion, has become empirically barbaric. The movement began in a revolutionary atmosphere and, like many revolutions, has constructed its principles a posteriori, rather than a priori. The subsequent fabric of generalizations has more intuitive appeal than logical coherence or commandingness.

The dividends of the revolution are obvious.

The psychological distance between investigations of perception, language, and thought, on the one hand, and studies of personality dynamics, on the other, has been shortened. This engagement will, we suspect, lead to a more cognitive framework for personality theory. The work of Kelly and Rotter is early evidence of this trend. Study of cognitive performances may put man back together by denying the artificial dissection of his psyche into categories labeled thinking, feeling, and willing. The association between quality of performance on a perceptual decision task (such as 10d-and-frame) and patterns of child-rearing lends a concrete vitality to this synthesis. These dividends from the work on cognitive variation are to be applauded. There are, however, several serious faults that deserve solemn concern.

First, there is the possibility that there is more method variance in the existing data than we normally acknowledge. Two of the parents of contemporary psychology—Hull and Freud—have taught their children to look closely at the agent of action (his history and his motives) in order to understand and predict his behavior. Correlatively, psychologists were rarely told to heed the context of the agent's actions. A hungry rat should run fast in any T-maze, a dependent child should ask for help from everybody. This cavalier dismissal of the critical and complementary roles of the social and impersonal environments has, regrettably, been inherited by many of the cognitive-style investigators. It is presumed that a field-independent person is field independent in all situations that require restructuring, an analytic child analyzes all visual material, a "sharpener" articulates sequential experience continually. This is probably the most serious fallacy in the interpretive structures that have been built around the work on cognitive variation.

The research reviewed suggests that the probability of a child analyzing a visual array is seriously dependent on the materials presented. A child can be analytic with one set of words and nonanalytic with another set of words or with pictures. The use of 10d-and-frame and embedded-figures tasks, which are masculine in their accoutrements, may be one source of the consistent sex differences in field independence. It is of extreme importance to determine the generalizability of the

within conclusions to test contexts that are less masculine or more feminine (e.g., an embedded-figures task that did not illustrate geometric forms but cooking utensils or flowers). The disregard of specific task materials implies that we may have been studying species of findings rather than genera or families. It is imperative that tasks sample a wide variety of contexts in order to demonstrate the power of the construct. In sum, it is not clear how much variance in test performance is specific to the test and how much is attributable to the hypothetical construct the procedure was designed to serve.

Although the names applied to theoretical constructs for "style" often have an exotic quality, it is possible that the phenomena they serve touch more familiar dynamic themes. Anxiety over error, attention distribution, expectancy of success or failure, and vulnerability to distraction are central to many of the test procedures utilized. The majority of the procedures reviewed present the subject with an "intellectual" task for which he believes there is a correct answer. Thus anxiety over intellectual competence and expectancy of success in the intellectual domain are always relevant variables controlling the final product. The emphasis on evaluative intellectual tasks as indexes of "style" should give us pause, for it does not seem intuitively reasonable that the basic psychological functions of human beings are most sensitively revealed in contexts in which the subjects believe their intellectual competence is being evaluated. Perhaps these procedures continue to be validated because they correlate with other test procedures that involve the same dynamic. Psychology gathers most of its human data (be they projective tests, memory-recall procedures, interviews, or paired-associate learning) from subjects whose behavior is geared to a strange examiner's reaction to or evaluation of their performance. This influence can be so pervasive that behavior in such potentially evaluative contexts may generate apparent construct validity within a diverse set of tasks.

Psychological phenomena possess the dual aspects of form and content. Motives, beliefs, expectancies, and standards are among psychology's central contents, but these contents are manifested in specific forms of behavior.

The operational probes we use to diagnose these contents must acknowledge those forms. Individual cognitive styles are almost always engaged when one attempts to explore a person's motives, expectancies, and standards. If we ignore these variables, our probes will provide noisy information. The small and

courageous cadre of scientists who have spent the last decade systematizing these dimensions have done a high service. It is clear that an individual's preferred fashion of interpreting, transforming, and reporting information will have to be a variable in any equation that seeks to explain him.

Addendum.¹ The Use of Multivariate Procedures in Developmental Psychology²

ROBERT B McCALL

Through much of its history psychology has tended to limit itself to univariate measurement and data analysis. One reason for this tendency resides in the fact that researchers have not been concerned about the possible diverse facets of a concept. For example, some investigators may use stated preference as a dependent variable and the research context does not require that stated preference be broken down into a set of component variates (e.g., interestingness, pleasantness). In these instances, univariate measurement is quite appropriate.

However, the modern *Zeitgeist* increasingly encourages the elementarization of phenomena and the investigation of constructs whose total conceptual implications are not efficiently encompassed by a single measurement. For example, in many contexts "socioeconomic status" is employed as a multivariate concept. Income, although a major component, does not envelop the total meaning of socioeconomic status because some semiskilled workers earn as much or more than highly trained people (e.g., foundry worker versus assistant professor). Education is certainly another facet of this global concept, but again it is not sufficient in itself because many people of only average education hold positions of influence and social prestige (e.g., some politicians). Consequently, by definition socioeconomic status involves a cluster of attributes, and therefore in cases in which the diverse contributions of these components are important, socioeconomic status should be indexed by a corresponding cluster of variables rather than by a single, easily obtained but insufficient measurement.

Alternatively, a construct may be quite unitary at a conceptual level but still benefit from multivariate measurement. For example, suppose that the research question centers upon whether or not an infant can discriminate between two visual arrays. The experimental logic dictates that if the subject consistently behaves differently in the presence of one than the other stimulus *in any way*, then it may be assumed that the infant detects the difference between the two patterns. The research question is not tied to specific responses but rather the search is for any behavioral

¹ This addendum was planned originally as a discussion of a method or technique that is particularly useful in studies of cognitive functioning and cognitive styles. However, as will become obvious to the reader, multivariate analysis is a method of wide applicability in all kinds of investigations of the development of individual differences.—Editor's note

² Portions of this paper were supported by the Research Council, Computation Center, and Institute for Research in Social Science of the University of North Carolina. In addition, Grant MH-8792 from the National Institute of Mental Health and Contract PH-43-65-1009 from the National Institute of Child Health and Human Development provided to Jerome Kagan, Harvard University, supported the empirical work described here. The author was an NSF Postdoctoral Fellow working with Professor Kagan when some of this research was conducted. Gratitude is expressed to Mark Appelbaum and Elliot M. Cramer for their guidance with the statistical analyses and interpretations and to Nancy Cole, Steven Cool, Fred Grote, Marshall Haith, David Jacobowitz, Lyle Jones, Jerome Kagan, and Stanley Mulaik for their helpful comments on earlier drafts of this paper.

difference of plausible psychological relevance. Therefore a multivariate approach may be a more powerful assessment technique since, because of the patterning of response variables (discussed later), it is quite possible to obtain no univariate effects but a significant multivariate difference. In this event, the univariate conclusion of "no evidence supporting discrimination" would be misleading in view of the multivariate result.

A third reason for considering multivariate procedures is to accumulate evidence on the interaction of dependent variables. For example, does the smile an infant displays to a visual stimulus have the same meaning when accompanied by vocalization as it does when it occurs alone? Psychologists often have used the analysis of variance because it offers information on the potential interaction among independent variables, yet the penchant for univariate measurement obviates the possibility of examining the pattern of interaction among dependent as well as independent variables. Even if several response measures have been taken, separate univariate analyses must be interpreted with the tacit assumption that each response occurs independently of every other response. Such a model is often untenable because responses cannot usually be extricated from their behavioral context without denuding them of much of their meaning. A response gathers psychological meaning as the cluster of its relationships and covariances with other independent and dependent variables matures. However, univariate measurement fails to provide a large portion of this information, and therefore the construct validity of our measures continues to be determined largely in an *a priori* rather than an empirical manner.

Consequently, a multivariate approach to issues in developmental psychology is likely to be profitable if the theoretical constructs would benefit from being broken down into their components, if the research question is so general that it is not tied to specific measures, and/or if the interactions among dependent as well as independent variables is of interest.

The purpose of this paper is to amplify these points by describing a few multivariate methods, illustrating them with sample data, and evaluating their advantages and disadvantages. There is no pretension to cover the

entire spectrum of such techniques (indeed, fact or analysis will be omitted completely), and no more mathematical and statistical sophistication will be required than an average acquaintance with correlation and the analysis of variance in its simpler forms. Consequently, the orientation of this paper is not to describe the procedures in such detail that they may be readily assimilated into the reader's methodological arsenal, but rather to sketch their purpose, general procedure, and advantages so that the researcher may acquire a sense for what these methods offer him as research strategies. Should the reader wish to apply these techniques, he is advised to do additional reading (see list of supplementary references) and consult a skilled proponent of these procedures *before* doing the experiment.

CANONICAL CORRELATION

Research Question

In many instances a researcher would like to know the degree of association between two *classes* of variables rather than between two *single* variables. Although the familiar multiple correlation reveals the degree of association between a class of measures and a single variable, the canonical correlation provides a direct extension of the multiple *R* to the case in which the dependent as well as the independent constructs are both represented by several rather than just one response measure.

For example, in a study of the distribution of attention of 4-month-old infants to a repeatedly presented standard stimulus (habituation phase) followed by a novel stimulus (McCall and Kagan, 1967), it was of interest to ask if there was any association between (1) the pattern of attentional responses during the habituation to the standard and (2) the pattern of attentional responses to the change relative to the familiar stimulus. That is, was there any relationship between the pattern of attention during the repeated presentation of a single stimulus and the attentional pattern elicited by the introduction of a novel stimulus? On the independent variable side (habituation phase), the first visual fixation, total fixation, time vocalizing, number of smiles, and habituation rate were measured. The attention variables were summed over

several presentations of the standard stimulus, and the habituation score consisted of the per cent decline in first fixation evidenced over repeated showings of the standard. Subjects who responded minimally from the beginning and therefore could not show habituation were not considered in this analysis. On the dependent variable side, the ratio of the attentional response given to the novel stimulus relative to all the stimuli (familiar plus novel) was computed for first fixation, total fixation, vocalization, smiling, and cardiac deceleration (see Graham and Clifton, 1966). The question was whether or not there was any relationship between attentional pattern during habituation and the attentional pattern to novel versus familiar stimuli when several measures of responsiveness both during habituation and during the novel-familiar stimulus presentations are weighted in a linear fashion in order to best reveal that possible relationship.

Statistical Procedure

The statistical task is to develop a set of weights c_i for the i independent variables and a set of weights k_j for the j dependent variables so that the correlation between

$$c_1X_1 + c_2X_2 + \dots + c_iX_i$$

and

$$k_1Y_1 + k_2Y_2 + \dots + k_jY_j$$

is a maximum

Example For boys, the results of the canonical analysis for the data just described are presented in Table A1. The bottom of the table indicates that the canonical correlation between attention during habituation and attention to a stimulus change was .97 for boys ($p < .006$) but a negligible .59 for girls ($p < .965$). Although these correlations seem high, recall that the variables of both groups have been linearly weighted in order to produce the maximum possible relationship. Since the sampling distribution employed for significance tests is appropriate to this weighted result, a canonical correlation of .59 may be quite nonsignificant.

Information permitting a more detailed interpretation of this result is provided in Table A1, which contains the matrix of simple correlations and the standardized weights determined by the canonical analysis. Looking at the weightings for independent variables presented in the last column, first fixation (.155), vocalization (.128), and habituation (.65) were given high positive values, where-

Table A1 Canonical Correlation between Attention during Habituation and Responsivity to Stimulus Change (Males)

	Univariate Correlation									Standardized Weights
	1	2	3	4	5	6	7	8	9	
Habituation										
First fixation										1.55
Total fixation	.78***									-.74
Vocalization	.50*	.21								.128
Smiling	.53*	.27	.73***							-.171
Habituation	.42	.19	.12	-.24						.65
Response to change										
First fixation	.60*	.42	.08	-.08	.55*					.50
Total fixation	.39	.32	-.04	-.02	.33	.82***				-.27
Vocalization	-.05	-.32	-.06	-.07	.48*	.13	.18			.11
Smiling	.07	.03	.48*	-.17	.27	.24	.00	-.14		.57
Deceleration	.45	.10	.58*	.34	.12	.20	-.02	-.38	.45	.42
	Canonical Correlation		Chi Square		df		p			
Males	.97		46.31		25		.006			
Females	.59		13.79		25		.965			

* $p < .05$

*** $p < .001$

as smiling and total fixation were assigned negative values. The interpretation of these weightings is quite analogous to the interpretation of beta weights in multiple correlation (for an excellent discussion of this subject, see Darlington, 1968). A high positive weight indicates that variation in such a variable contributed to the multivariate relationship. Thus first fixation, vocalization, and habituation were important variables in the present analysis. A large negative weight may have one of several meanings. First, a negative coefficient may be obtained if the variable is inversely related to the composite score which the analysis computes for that set of variables. In this case such a variable would have negative bivariate correlations with some of the other measures in its set. Second, it is possible for a variable to be positively correlated with the members of its set but still be assigned a negative weight by the analysis. In this event, the interpretation may be that a portion of the variance of the negatively weighted variable is shared with a variable that otherwise makes a positive contribution to the canonical relationship but that this common variance is irrelevant to the multivariate relationship. Within the context of multiple correlation, a predictor assigned a negative weight is called a "suppressor" variable if the variance it shares with another predictor "suppresses" the capability of that measure to predict the criterion.

Consider the two examples of a suppressor-like variable contained in the sample data. First fixation (1.55) is a positive contributor to the canonical relationship while total fixation (-.74) was given a negative weight, yet the two measures correlate .78. This simple correlation is not surprising in view of the fact that total fixation includes first fixation as one of its components. Consider a psychological interpretation to illustrate how the negative weighting given to total rather than first fixation could be interpreted in terms of a suppressor effect.³ In the experimental situation, there is very little else for the 4-month infant to do except look, and almost nothing else to

look at but the experimental stimulus. Therefore a certain amount of baseline or stimulus-irrelevant looking occurs. Of course, some looking is governed by the nature of the stimulus that the experimenter presents. It is likely that first fixation reflects more stimulus-controlled looking because it is the infant's initial glimpse of the newly introduced display, whereas total fixation may be influenced relatively more by the baseline looking tendencies of the infant, which are largely extraneous to the nature of the stimulus. Thus first fixation becomes a more salient contributor to the canonical relationship with responsiveness to a change in the quality of stimulation. Further, first fixation is likely to be influenced to a lesser but nonzero extent by the baseline looking tendencies of the subject and the simple correlation between first and total fixation may reflect, in part, that shared variance. Therefore if this variance which first fixation shares with total fixation which is irrelevant to the response to stimulus change is subtracted out by weighing total fixation negatively, then the predictive power of first fixation is sharpened.

In a similar situation involving a suppressor-like variable, vocalization (1.28) during the habituation phase was a positive contributor to the canonical relationship, whereas smiling was not (-1.71), even though smiling and vocalization were highly correlated (.73). In this instance, the analysis has suggested that a component of the vocalization response which is related to smiling does not contribute to the canonical correlation. Thus vocalization becomes a better contributor if the irrelevant component it shares with smiling is subtracted from it.

On the other side of the relationship the weightings for dependent variables presented in Table A1 show that in terms of the responsiveness to change, smiling, first fixation, and cardiac deceleration are the major variables contributing to the canonical correlation with habituation pattern.

The fact that the canonical relationship was very high for boys (.97) but almost significantly absent for girls (.59, $p < .96$) suggests that these variables play different roles for the two sexes. Since other evidence (McCall and Kagan, 1967) suggests that the girls did indeed respond to the changes, this result implies that boys and girls express

³ Since first fixation is a part of total fixation, the confounding of these measures represents the best explanation for the observed result. However, the psychological explanation is presented to illustrate the potential function and interpretation of a suppressor-like variable.

their responsivity to stimulus change differently. That is, because the pattern of relationships among these variables differs as a function of sex, a smile or a vocalization during the habituation phase may carry a different message for boys than it does for girls.

To summarize, the canonical analysis suggested that for those subjects whose attentional responses provided an opportunity for habituation to a repetitively presented stimulus to occur, the pattern of habituation was related to responsivity change for boys but not for girls. The habituation measures primarily contributing to such a relationship were first fixation, vocalization, and magnitude of habituation, with total fixation and smiling acting in the manner of suppressor variables. The response to a change was reflected in smiling, first fixation, and deceleration. Further, it appears that these variables may carry a different meaning for the two sexes.

Additional Applications

Canonical correlation could be used in longitudinal studies of personality and intellectual ability. For example, do maternal attitudes of protection, restriction, hostility, and acceleration relate to the child's passivity, emotional dependency, withdrawal, etc? Which of these variables weighs most highly in this relationship? What is the extent and pattern of the possible relationship between maternal attitudes and the child's intellectual abilities as measured by an extensive test battery? What is the nature of the potential relationship between personality and ability measures?

Is it at all possible to predict later behavior from neonatal or infant assessment? In this regard, it may well be that one of the reasons why infant measures have largely failed to correlate with later behavior is that the predominant strategy has been to use univariate techniques. Examination of the pattern of interactions among variates with canonical correlation may prove valuable in this context.

MULTIPLE DISCRIMINANT ANALYSIS

Research Question

If a researcher had two or more distinct groups of subjects with several measures on each subject, it might be of interest to ask whether the groups can be significantly dis-

criminated on the basis of a derived variable composed of a linearly weighted combination of the several dependent variables. A multiple discriminant analysis performs this task.

For example, in the previously described experiment (McCall and Kagan, 1967), subjects were classified into the following groups on the basis of their looking responses to the repetitively presented stimulus during the habituation phase:

1 *Rapid Habitulators*—subjects whose first visual fixation to the presentation of a stimulus declined markedly with repeated presentations of that same stimulus.

2 *Slow Habitulators*—subjects whose first fixations did not decline over trials.

3 *Short Lookers*—subjects whose first fixations were always of such extremely short duration that they had no opportunity to demonstrate habituation because of their low initial values.

The question was posed as to whether these three groups, selected as a function of their first fixation to the standard stimulus, could be discriminated from one another on the basis of the nonlooking dependent variables of resting heart rate (heart rate taken during the interstimulus interval), the time spent vocalizing during the habituation period, the number of smiles during the habituation period, educational attainment of the infant's parents, and the weight of the subject.

Statistical Procedure

Algebraically, the purpose of the multiple discriminant analysis is to determine the set of weights or coefficients c_i for the several dependent measures X_i which will separate the groups to the maximum extent. For example, if the composite or discriminant function is called Y , and if there are two groups to be discriminated with four dependent variables, the analysis will produce a discriminant function of the form

$$Y = c_1X_1 + c_2X_2 + c_3X_3 + c_4X_4$$

such that the mean values of Y for the two groups will be maximally different. In terms of variance, the analysis selects a set of weights which will maximize the between-group variance relative to the within-group variance in the derived variable Y .

Geometrically, Cooley and Lohnes (1962) diagram the procedure for the case of two

Fig A1 Diagram of a geometric interpretation of a discriminant analysis (see text, from W W Cooley, and P R Lohnes, *Multivariate procedures for the behavioral sciences*, John Wiley & Sons, Inc., New York, 1962)

groups with two dependent measures in the manner of Fig A1. The two variables X_1 and X_2 are on the abscissa and ordinate, respectively, and the two groups I and II are represented both by their centroids (points) and by their 90 contours (the ellipse surrounding each centroid, which encloses 90% of the frequencies of each group). If a line a is drawn through the intersection of the two contours and the discriminant dimension Y is drawn perpendicular to this line, then the projections (discriminant scores) of the two groups on the discriminant dimension will be maximally separated (there will be the least possible overlap between the distributions).

In short, the multiple discriminant analysis produces a set of coefficients or weights for the several dependent measures which best separate or discriminate between the groups on this derived dimension. The between-group variance is maximized relative to the within-group variance.

Example The boys' data from the McCall and Kagan (1967) study described previously were submitted to a multiple discriminant analysis to determine if the three groups (rapid habituators, slow habituators, short lookers) could be discriminated on the basis of a linear combination of five nonlooking variables. The results are given in Table A2,

which presents the means and standard deviations, within-cell correlations (correlations of dependent variables with the effect of the grouping parceled out), the univariate F -tests and associated probabilities corresponding to a one-way analysis of variance on each variable separately, and the discriminant function coefficients (coefficients for each standardized dependent variable, which when multiplied and summed yield the best discriminating composite score).

The first point to note about the results is that not one of the univariate F -tests revealed a significant difference between the three groups, although the heart rate measure reached the .07 level. In contrast, the multiple discriminant function was significant ($F = 2.50$, $df = 10, 36$, $p < .02$), suggesting that the groups could be discriminated on the basis of a linear combination of the dependent measures. It is possible to obtain a significant multivariate discrimination without significant univariate F s because the multivariate analysis considers the relationship among the dependent variables. A collection of univariate tests does not permit an interpretation in which dependent response measures interact with each other. In contrast, the multivariate analysis permits assessment of the possible pattern of interactions between various facets of behavior. With this method, responses are not artificially extricated from their behavioral context, and although a given manipulation or condition may not be clearly manifested in a single variable, it may be observed in the pattern of several dependent measures considered as a conjunctive display (although the "display" is a function of the variables selected by the experimenter).

To interpret this result in more detail, consider first the standardized discriminant scores in Table A2. Smiling (1.43) and heart rate (.62) were given positive weights. In terms of the means of the groups on these variables, the slow habituators smiled the most while the short lookers had relatively slow resting heart rates. However, vocalization (-1.66), education (-.81), and body weight (-.41) received negative coefficients. Again, a negative weight may imply that the variable acted in the capacity of a suppressor. That is, such a variable correlates with a nondiscriminating component of a positive contributor to the discrimination and thus should be sub-

Table A2 Discriminant Analysis of Habituation Phase for Boys

	Variable				
	Heart Rate	Weight	Educa- tion	Vocali- zation	Smiling
Means and Standard Deviations					
Slow habituation (N = 9)					
\bar{X}	149.4	224.0	6.8	7.3	1.0
<i>s</i>	12.3	86.4	3.1	11.3	1.4
Rapid habituation (N = 4)					
\bar{X}	150.4	264.8	6.8	7.6	0.0
<i>s</i>	10.0	25.0	4.3	11.3	0.0
Short fixation (N = 12)					
\bar{X}	140.0	240.8	9.0	8.8	.5
<i>s</i>	8.0	18.3	2.2	11.2	1.0
Within-Cell Correlations					
Weight	-.19				
Education	.08	-.17			
Vocalization	.15	.10	-.49*		
Smiling	.01	.27	-.31	.81***	
Discriminant Analysis					
Univariate <i>F</i> (<i>df</i> = 2,22)	2.95	.79	1.73	.05	1.22
<i>p</i> less than	.07	.46	.20	.96	.31
Standardized discriminant coefficients	.62	-.41	-.81	-1.66	1.43

* $p < .05$ *** $p < .001$

tracted from the contributor in order to sharpen the discrimination between criterion groups. Consider vocalization and smiling. Smiling is a positive contributor to the discrimination (1.43) but the within-cell correlations in Table A2 show that vocalization correlates .81 with smiling. Since vocalization is given a negative weighting by the analysis, the implication is that the smiling variance shared by vocalization is irrelevant to the discrimination and subtracting it sharpens the separation of the groups. Considered from a psychological point of view, a smile is often observed after an infant looks at a stimulus for a few seconds without any accompanying vocalization. This is sometimes regarded as a response of recognition. However, on other occasions a child will become excited and as a result he will both vocalize and smile in temporal contiguity. These latter smiles, correlated with vocalization, may be irrelevant to the discrimination between groups, and the discriminant analysis may be highlighting this fact.

In summary, although no single univariate test attained significance, the multiple discriminant function did. It would have been misleading to conclude on the basis of the univariate analyses alone that the nonlooking variables were unrelated to the three habituation groups. Further, it would also have been incorrect to conclude that although the univariate *F* for vocalization was substantially less than 1, that vocalization was unimportant to the discrimination between groups because vocalization did act as a suppressor. This result further punctuates the fact that in many cases dependent measures must not be viewed in isolation but rather in the context in which they occur. A variable extracted and isolated from its behavioral environment loses some of its meaning and power as an index of psychological events.

Additional Applications

Discriminant analysis could find application in the many instances in which the independent variable falls neatly into discrete groups.

For example, the entire area of sex differences could benefit from discriminant analysis. What is the difference between the sexes when ability measures are considered jointly? What is the nature of the sex difference in personality traits? In what ways do blind and seeing or deaf and hearing children differ in mental abilities or personality traits? What is the pattern of differences between normal and mentally retarded children on ability measures, personality traits, or performance indices?

MULTIVARIATE ANALYSIS OF VARIANCE (MANOVA)

Research Question

Multiple discriminant analysis is directed at outlining how separate groups of subjects could be discriminated. The same general orientation may be taken toward the groups in an analysis of variance design. Indeed, a one-way multivariate analysis of variance is multiple discriminant analysis, but the same procedures may be applied to designs involving more than one independent variable—how to determine how the several dependent variables may be weighted to produce the biggest effect for factor A, for factor B, and for their interaction. Viewed from another orientation, MANOVA is simply the analysis of variance using several rather than just one dependent variable in which these variates are weighted to provide the maximum possible effects.

To illustrate with data from Kagan and McCall (1967), 4-month-old boys and girls viewed a series of four facelike, three-dimensional stimuli (for pictures of the stimuli see Kagan, Henker, Hen-Tov, Levine, and Lewis, 1966). First fixation, total fixation, vocalization, smiling, and cardiac deceleration were summed over all stimuli. Collectively, these measures indexed the gross attentional characteristics of the child. With reference to specific stimuli, some children gave longer first fixations to a faithful representation of a male face, while others looked longer at a scrambled rearrangement of the same features. Was there any difference in terms of gross attentional characteristics between boys and girls and between those subjects who looked longer at the regular face than those who looked longer at the scrambled version? Was there an interaction?

Statistical Procedure

The multivariate analysis of variance computes a set of weights separately for each factor in the analysis of variance design so that after the total variance has been partitioned, the weighted combination of the several dependent variables produces a maximum effect. In this sense a discriminant analysis is a one-way multivariate analysis of variance. In addition to the partition of variance, a two-way MANOVA is composed of three discriminant analyses—one for each of the main effects and one for the interaction.

Example The MANOVA for the data described above is reported in Table A3. Only the sex effect was significant in the multivariate case ($F=3.59$, $df=6, 82$, $p<.003$). The standardized weights show that cardiac deceleration and smiling contributed most to the sex differences, boys decelerating and smiling more than girls. The F for deceleration was the only univariate test reaching significance ($F=18.22$, $df=1, 87$, $p<.001$), even though smiling as well as deceleration received a positive weighting of some consequence in the multivariate case. Further, although first and total fixation each had univariate F s that approached significance ($p<.14$), the MANOVA assigned them weights of essentially zero (.09 and .04). This result derives from the fact that the pattern of correlations between fixation times and deceleration (the major contributing variable) and the variability of fixation relative to deceleration are such that deceleration performs the discrimination between sexes more efficiently than fixation times. Therefore when all the dependent measures are considered jointly and the best selection is required, even though fixation times may reflect sex differences in their univariate cases, the MANOVA minimizes their apparent contribution because deceleration and smiling make the same sex discrimination more efficiently. This result points up another advantage of multivariate analyses: the statistical procedures not only compare the several dependent variables being analyzed in terms of their joint contribution to discrimination between groups, but they also determine the most efficient combination of variables for this purpose. Therefore, if one were restricted to a few dependent variables with which to assess sex differences

Table A3 Sex \times Regular-Scrambled Face Manova on Gross Attentional Measures

	First Fixation	Total Fixation	Number Fixes	Vocalization	Smiling	Cardiac Deceleration
Means						
Boys						
Regular	78.8	156.6	28.9	18.7	4.6	15.4
Scrambled	75.9	150.2	29.3	25.0	7.1	14.0
Girls						
Regular	54.8	136.8	37.5	20.7	2.3	10.6
Scrambled	70.6	140.0	26.9	17.4	3.7	10.6
MANOVA						
Sex effect ($F = 3.59$, $df = 6, 82$, $p < .003$)						
Standardized weights	.09	.04	.07	.13	.41	.94
Univariate						
$F(df = 1, 87)$	2.27	2.27	.83	.65	1.57	18.22
p less than	.14	.14	.37	.42	.21	.001
Regular Scrambled ($F = 1.00$, $df = 6, 82$, $p < .43$)						
Sex \times Reg -Scr ($F = 1.38$, $df = 6, 82$, $p < .23$)						

in this setting, cardiac deceleration and smiling would be the most efficient selection.

Since variables are weighted in multivariate analyses, replication of results is more important here than for univariate procedures. Four-month-old infants also viewed a series of two-dimensional slides composed of a photograph of a male face and a collage of that face (Kagan and McCall, 1967, for stimuli see Kagan et al., 1966). Again, on the basis of their first fixation to the photographs, infants could be classified into those looking longer at the regular versus those looking longer at the scrambled collage of the photographed face. A sex \times regular-scrambled MANOVA using the same dependent variables as above produced results that were almost identical with the prior analysis: deceleration (.94) and smiling (.39) again received the highest weightings, indicating that boys decelerated and smiled more than girls. The other variables were assigned weights near zero. Similarly, no other effects were evident.

Additional Applications

If the design has more than one independent variable and several dependent variables, MANOVA may be appropriate. What is the pattern of intellectual abilities in different socioeconomic status groups of several ethnic-racial subcultures? What is the nature of the

effects of sex and socioeconomic status upon various facets of language development? In what patterns of personality traits are early and late maturing boys and girls different? What is the cluster of cognitive abilities which distinguishes reflective or impulsive boys and girls? Multivariate techniques may be used with experimentally generated as well as observational data. Not all measures of learning (number correct, trials to criterion, etc.) reflect the same information, and therefore analysis of variance designs of children's learning which employ several dependent measures may find MANOVA profitable.

CRITICISMS OF MULTIVARIATE PROCEDURES

Multivariate techniques are often questioned by researchers who are somewhat unfamiliar with the procedures. A few critical questions are now discussed.

Doesn't weighting several variables to produce the greatest possible correlation or discrimination capitalize upon chance? Yes, it does to some extent. Although the sampling distributions used to test multivariate effects are appropriate for the number of variables involved and also to the weighted statistics being evaluated, multivariate results need experimental replication just as beta weights and R s in multiple regression demand replica-

tion Replication may take the form of redoing the experiment and the analyses, or as in the case of multiple regression the obtained weights may be assigned to the dependent variables produced by a second group of subjects (or second half of the total sample) and univariate analyses performed on the resulting derived composite scores The need for such replication varies somewhat with the level of detail one wishes to highlight in the interpretation of multivariate analyses It is considerably less risky to emphasize the fact that a canonical relationship or a discrimination was or was not obtained than to focus conceptual and theoretical importance upon minor details, such as whether variable A was assigned a weight of 40 or 50 Thus by placing more confidence in the general results and less in the specific details, one is less likely to build his house on sand Nevertheless, although sometimes tedious, replication (even splitting the sample into two parts) is always valuable, and the researcher must decide if the advantages of multivariate procedures (discussed later) are sufficient to make replication worthwhile

Is it not a somewhat circular and biased procedure to determine whether or not a relationship or a discrimination exists by employing methods which are designed to produce the maximum possible effect? The weighting procedure is precisely analogous to that which exists in multiple correlation The techniques seek to determine whether there exists *any* linear combination of response variables that produce a significant effect Since there are many possible combinations of these measures, the procedure picks only the weightings that generate a maximum effect, testing the resultant statistic against a known distribution, which reflects the fact that there are many possible combinations of which the maximum has been selected If the maximum value is not significant, then a relationship or discrimination probably does not exist Conversely, if the maximized statistic is significant, it is incumbent upon the researcher to make conceptual sense of this fact This interpretative phase may require a theory or additional empirical work, but it is not fundamentally different from any other research situation—the statistical techniques attach a probability to a given statement but they do

not provide a psychological interpretation for the result

It seems that one has to resort to univariate procedures in order to interpret the results of multivariate analyses, so why perform the multivariate tests in the first place? Although multivariate procedures are direct extensions of their univariate analogues, they pose a somewhat broader research question Is there any relationship at all between this *class* of variables and another *class*? Can certain groups be distinguished in any way by this *group* of measures rather than by a single variate examined in isolation? Further, since multivariate results reflect the pattern of relationships among the measures, the interpretation made of the meaning and salience of any single variable may be quite different as a result of using multivariate as opposed to univariate analyses Thus, although it is certainly true that univariate tests help to interpret multivariate results, the two procedures often provide different types of information and even suggest different implications for the same research questions

Since the results of multivariate procedures are frequently so intricate, qualified, and without convincing psychological interpretation, don't they confuse the issue more than they clarify it? There is no doubt that parsimony is a goal of science, but the law is to be applied only when the choice is between two equally plausible alternatives It is one thing for the scientist to invoke parsimony in a decision without an alternative basis of selection, but it is quite another to *impose* parsimony a priori Occasionally, the lack of parsimony exists in nature Further, there is no question that experimental control is more desirable than statistical control, but in the many cases in which experimental and scientific knowledge are not yet adequate to the task, it appears presumptuous for the scientist to a priori select a single measure or to ignore the interrelationships among the several dependent variables at hand Finally since responses do not ordinarily occur in behavioral isolation, the simplicity of methods relying upon the unnatural extrication of single measures from their behavioral context may be deluding Therefore the question should not be one of the facility of interpreting multivariate results but whether or not their complexity appropriately matches the complexity of nature

Moreover, as psychology investigates increasingly more complicated phenomena it must also accept the responsibility of evaluating them in all their intricacy

Doesn't the result of a multivariate analysis depend upon the variables selected for inclusion in that analysis? Yes, it does, but the selection of dependent measures is always a major decision which determines the outcome of any experiment Is the result of a multivariate experiment any more a spurious product of the cluster of dependent measures chosen than the result of an experiment in which an a priori decision restricts the empirical evidence to a single measure?

What if the variables should be combined in a nonlinear rather than linear fashion? Since most researchers do not run a nonlinear measure of correlation (e.g., *Eta*) for every Pearson *r* they calculate, nonlinearity does not appear to be a de facto concern when using other techniques However, the assumptions of any model require examination, and the question of linearity should be investigated empirically However, considering the pervasive use of linear models in psychological research, there is little reason to question this assumption more in the context of multivariate procedures than in most univariate methods (e.g., Pearson *r*, the analysis of variance)

ADVANTAGES OF MULTIVARIATE METHODS

A first advantage is that multivariate methods address general questions of relationship and discrimination If the researcher wishes to know if a relationship exists between two multifaceted concepts or whether or not several groups differ in any way on a set of dependent measures, then multivariate procedures may be appropriate For example, is

there any relationship between maternal behavior and later dependency in the child? Can delinquent boys be discriminated from nondelinquents on the basis of parental disciplinary techniques? Multivariate procedures, because they consider several measures in concert, ask a somewhat broader question than their univariate counterparts

*Second, if several variables possessing some psychological cohesiveness are measured, multivariate procedures are preferred over a proliferation of univariate tests in much the same manner as the analysis of variance is preferred over several *t*-tests*

Third, most responses should not be viewed in isolation but as a conjunctive display There are several implications of this proposition First, the power of the analysis is often increased by using multivariate methods As has been illustrated, a multivariate result may be significant without obtaining significant univariate *F*s (though the reverse is also possible) Second, the pattern of relationships or interactions among the dependent variables constitutes important psychological information The relative weightings of variables and the detection of suppressorlike measures contribute another dimension of information Third, the knowledge thus gained by examining the pattern of several variables adds to the construct validity and interpretation of the dependent measures themselves

In summary, methods of data analysis provide the researcher with models for the behavior he observes The major feature of multivariate models is that they make provision for considering the interaction among dependent (as well as independent) variables As such, they allow for examination of a more global behavioral display rather than artificially excising variables out of their natural context

19. *Cognitive Development and Education*

WILLIAM D. ROHWER, JR.

The study of cognitive development and the education of children have much in common. In both, the object of concern is the individual over a considerable portion of the human life span. Although the particular age interval falling within the purview of the two enterprises may differ somewhat, the amount of overlap is still substantial. The ages that fall within the compass of education may be limited to those covered by the median years of formal schooling, say kindergarten through grade 12. Or the education interval may be extended to cover one or two pre-school years at the lower end of the age scale and four to eight years of higher education at the upper end. By either definition, the interval does not cover a span of years sufficient to circumscribe the major interests of many psychologists working in the field of cognitive development. The concern of those interested in early periods of life exceeds the lower educational age boundary and the concern of psychologists interested in maturity and aging exceeds the upper educational age boundary. But the concerns of educators themselves often overrun the conventional boundaries of formal education. A number of university departments of education recognize as formal specialties both early childhood education and adult education. Thus the generalization stands that both education and the psychology of cognitive development largely share the same object of concern.

Educators and psychologists interested in problems of cognitive development have more in common than the object of their concern. They also share a principal interest in the same aspects of human functioning—the intellectual aspects. Even though “intellectual”

is as slippery a term as “cognitive,” it does serve to underline a relatively general consensus that the major emphasis both in education and in cognitive development is not upon the social, emotional and physical aspects of human beings. The educator’s intent is to institute those conditions that insure the acquisition of intellectual competence across the widest possible range of human beings and the psychologist’s is to specify determinants of intellectual competence in all human beings.

With so much substantive overlap between concerns in education and in cognitive development, effective commerce between the two should be guaranteed. This expectation is strengthened by two additional conditions prevailing in education and in the psychology of cognitive development. The schools are beset by problems that obstruct the attainment of the educator’s goal of insuring the achievement of intellectual competence by all students. Consequently schoolmen, for the most part, are open to suggested solutions for these problems. On the other side, psychologists working on cognitive development have already obtained partial verification of some propositions as to the determinants of intellectual competence through research conducted under laboratory conditions. To complete the task of verification, such research must be extended to more naturalistic conditions, conditions that may be found in more appropriate form in the schools than anywhere else. Such psychologists are also faced with the task of illuminating the very large number of remaining mysteries of cognitive development. Work on this task might well begin with observations made under conditions that explicitly

direct the child toward intellectual activity in a relatively regular and orderly manner, that is, under school conditions. Again, it seems warranted to conclude that profitable commerce between education and the psychology of cognitive development is assured.

But *commerce* between the two fields can have a variety of meanings, it can mean a great deal of interpenetration resulting in mutual progress or it can mean little more than conversations of varying degrees of formality with very little consequence. Our consideration of this question will be one-sided: we shall attend principally to the matter of exports from the psychology of cognitive development to education. Within this limitation, the question of commerce may be reduced to two forms: "Does the psychology of cognitive development have relevance for education?", and "Does the psychology of cognitive development have contributions to make to education?" As we shall see, the relevance of cognitive development for education is easier to establish than the assertion that a substantial contribution to education will result from its study.

If the proposition is accepted that the greater the amount of information about children available to schoolmen, the better the chances of improving educational practice, then the products of the psychological study of cognitive development are of obvious relevance. In the weak sense of the term "relevance," virtually all theory and research qualify, subject only to the restriction that it be valid. Not only teaching, but curriculum design, production of educational materials, and other educational functions could benefit from the information produced by psychologists in the course of their work on problems of cognitive development. Even psychological investigations that are planned, conducted, and completed without regard for educational problems may have relevance for educational practice. But it is a separate question whether such investigations can effectively contribute to education. Establishing educational relevance requires only a modicum of facility in conceiving of relationships between education and cognitive development, whereas a contribution to education requires that the products of psychological theory and research result in alterations of educational practice and of its outcomes. It is

unlikely that such changes can be accomplished without an explicit intention to do so. That is to say, theory may have to be rewritten in educational terms and research may have to be redesigned with an educational context clearly in mind. When theory and research are revised in this manner, their components will have reference to school variables rather than to laboratory conditions, to classroom procedures rather than experimental procedures, to teachers and students rather than experimenters and subjects, and to long- rather than short-term objectives. This does not mean the present form of education must be taken as unchangeable but that the matter of effecting educational change involves more than excellence in the construction of psychological theory and research.

So far, each of the topics relating to the possibility of interplay between education and the psychological study of cognitive development has only been alluded to in general terms. Before proceeding to a discussion of particular aspects of available psychological theory and research that have the potential for making educational contributions, or, at least, for being educationally relevant, these issues of the relationship between the two fields deserve a more detailed treatment.

EDUCATION, PSYCHOLOGY, AND COGNITIVE DEVELOPMENT

Education is plagued by problems. They are widely recognized and publicly proclaimed by both educators and laymen in speeches and in writing, in books and in periodicals, in professional journals and in popular magazines, in reports of governmental agencies and of private foundations. The broad consensus that problems exist begins to dissolve when it comes to specifying the nature of the problems and to recommending possible solutions. Nevertheless, the events that constitute evidence of the existence of problems permit a generalization. There is enormous variation in the outcomes of schooling, whether that variation is measured in an absolute way in terms of failures to reach some agreed upon standard of accomplishment or, in a relative way, in terms of differences among individuals in the extent to which they attain any particular level of accomplishment. Consider, for example, the

substantial (although decreasing) proportion of individuals who do not complete a high school education, that is, the widely-publicized drop-out problem. Or, in a more relative vein, consider the striking variations among individuals in performance on a standardized examination of educational-intellectual achievement such as the Armed Forces Qualification Test. In 1966, the proportion of persons who failed (those scoring below the 10th percentile) the so-called mental test for entrance into the Armed Forces was 11.5% (Department of the Army, 1967). Another feature of these variations compounds the problems for the schools within this society, this is the fact that the proportion of failure is not equal across all groups within the culture. For example, 27% of Negroes failed the armed services mental test, whereas the proportion for whites was only 4.3% (Department of the Army, 1967).

Variations of this sort and of this magnitude emerge earlier than at the secondary-school level. Within a single school system, for instance, the average performance of junior high school students on standardized tests of reading, writing, and arithmetic achievement may be above the 95th percentile in a predominantly white school, whereas that of students in a predominantly Negro school may be below the 15th percentile. To continue on down the age scale, the performance of first-grade children on tests designed to assess readiness for initial formal reading instruction results in similar variation in rates of failure across ethnic and socioeconomic (SES) groups. Thus the problem is pushed back further to the point where some are tempted to conclude that eventual drop-outs can be detected at preschool ages (Jensen, 1968). If this is so, then the schools face the task of effectively upsetting these predictions by means of the practices they implement for the education of children. An enormous task it is, given the variation that exists when the children first enter the formal educational system and given that schooling appears to amplify rather than reduce the magnitude of individual differences (Anastasi, 1958).

The response of both educators and interested laymen to these problems has been substantial and varied. Unprecedented amounts of money have been earmarked by govern-

mental agencies and private foundations for experimentation in educational practice in the schools. New techniques of instructional organization have been initiated from team teaching to reduced numbers of students per classroom and from elaborate homogeneous grouping of students to ungraded schools with heterogeneous grouping. New curricula have been developed and introduced in the schools, especially in mathematics and the sciences. Special services have proliferated and the ranks of those engaged in them have been increased: school psychology, counseling, speech therapy, remedial reading, special teachers of the retarded, and so on. In most of these specialties, practice requires that expertise come into play only after problems emerge in specific children, and there is no paucity of work to be done in any of the fields mentioned. Preventive approaches have been initiated with preschool and early elementary school children, notably in the federally financed Project Headstart.

In some cases, these responses to educational problems are too new for proper evaluation and in other cases specific programs have been successful, some marginally, others impressively so. Still, the general result has been little change in the range of variability in the outcomes of education (Stephens, 1967). The problems still persist and for those directly involved—teachers, parents, students—the problems are more pointed than these summary remarks can make clear. There is no mistaking the dedication of those bending their efforts in the search for solutions, and yet the goal still exceeds the struggle toward it.

Schoolmen, in large numbers, know and admit that the problems exist. As educators, they are eminently receptive to potential solutions. The members of social groups among whose children school failure is disproportionately large insist upon changes in educational practice that will substantially reduce the disparities. Broad press coverage is given to vocal critics of the schools. As a consequence of these and other conditions, schooling is open to innovation and to substantive contributions to educational practice almost without regard for their source. Consider, for example, the adoption by one school district of a technique originally developed for the retraining of mentally retarded children as a

part of their program for culturally disadvantaged students. Whatever the merits of the technique in the case of the population for which it was developed, there is little indication that it is even relevant for those children with whom this school district must deal. Nevertheless the practice has been implemented eagerly by those involved.

The situation in education clearly warrants optimism as to the kind of reception relevant psychological theory and research might receive. The present situation also justifies optimism about the prospect that the work of many psychologists will be directed toward educationally relevant problems. Historically it is possible to discern three loosely defined periods since 1900 with respect to the relationship between psychology and education. The first was marked by substantial efforts on the part of psychologists to speak to matters of classroom practice as they directly affected learning (Thorndike, 1931, Dewey, 1916). It was also marked by the beginning of efforts to devise tests to measure the effects on school learning of previous educational experience and of abilities brought to that experience. But the latter movement was only in its infancy during this period, whereas it dominated what may be distinguished as the middle period. During the first period, a truly major figure in the history of experimental psychology, E. L. Thorndike, addressed himself to problems of educational practice and did contribute to changes in practice. By contrast, during the middle period, the major figures among psychologists who contributed to changes in educational practice came from the fields of differential psychology and measurement. Eminent investigators such as Terman and Thurstone along with Wechsler and many others promoted the remarkable growth in the use of aptitude tests in schools.

The alliance between the psychological testing movement and the schools grew strong and commerce between the two was frequent and substantial. Three major functions were served by testing. First, tests permitted objective, systematic evaluation of changes in students as a function of age and/or education. Second, it became possible to detect differences among individuals with respect to educational promise. And, third, it became feasible to reduce the magnitude of variability within classroom units by classify-

ing children with respect to what the tests measured and, for the purposes of instruction, grouping them relatively more homogeneously than had previously been possible. The first of these functions prepared the way for the more recent awareness of the magnitude of school failure. The availability of relative achievement data made visible the great extent of variation in educational outcomes. The second function was a necessary prerequisite for the third one, that is, the grouping of children according to tested ability. Of the three functions, it was the third that had the greatest impact on classroom conditions of learning. Even here, however, the impact was indirect—it had minimal reference to procedures used in the classroom. Its influence was on the composition of the membership of classroom units or of subunits within classrooms.

A more advanced potential function was not quickly realized in practice during this middle period and still remains only partially fulfilled. The development of reliable instruments for the classification of children in terms of intellectual ability and achievement, along with the corollary development of grouping practices, permitted the systematic design of different curricula, tailored to accommodate the individual differences revealed by testing programs in the schools. The term curricula as used in this context does not refer to widely divergent educational programs as exemplified by the difference between an academic and a vocational curriculum. Rather, the reference is to cases in which the educational objectives for several different categories of students are virtually identical, but the means for attaining them are varied to take account of the revealed ability and achievement differences between the groups. This is not to say that no curricular variations were introduced by the inception of classificatory techniques and grouping practices within the schools, for these did indeed ensue. But, for the most part, these variations consisted in simply diluting or enriching the content to be mastered. With a few exceptions, say, for the mentally retarded and the neurologically handicapped, minimal variation was introduced into the methods by which schoolmen attempted to forward the progress of students toward common educational objectives.

During the second major historical period

identified by the influential role of psychological testing, experimental psychologists were largely concerned elsewhere, not with problems of educational practice and school learning. For example, the major figures in the field, Hull and Tolman, were almost entirely concerned with laboratory research, phenomena produced in the laboratory, and the building of theories in which laboratory restrictions provided the boundary conditions.

With the onset of the third discernible historical period, the attention of some established figures within experimental psychology gradually began to shift to phenomena observed in school settings and many young psychologists embarked upon their careers with considerable sensitivity to educational phenomena. A few examples will suffice to illustrate the point. Among established psychologists, increasing attention to education is shown in the publication of "The Science of Learning and the Art of Teaching" by B. F. Skinner in 1954, *The Process of Education* by J. S. Bruner in 1960, and *Conditions of Learning* by R. M. Gagné in 1965. Among psychologists whose doctoral degrees were taken after 1950, A. R. Jensen, J. Kagan, and A. W. Staats illustrate the magnitude of interest given to educational problems from a psychological viewpoint. Finally, the growth in membership of the Division of Educational Psychology between 1950 and 1966 substantially exceeded the average of that in the Divisions of General, Experimental, and Developmental Psychology (1431 versus 456).

Despite the impressive evidence that can be marshalled to demonstrate an increasing recognition by both schoolmen and psychologists of the *relevance* of psychological theory and research for education, the possibility that such theory and research will make substantial *contributions* to education is still quite uncertain. There are two general classes of reasons for this uncertainty. The first concerns the character of the educational system itself and the second has to do with the feasibility of reworking what is essentially psychological, not educational theory and research within the framework of the conditions of educational practice. On the latter point there is sharp divergence among psychologists as to the strategies that should be followed in order to permit contributions to be made, as will be documented shortly.

It is possible to single out instances in which particular schools or particular school systems have readily adopted new educational procedures. Nevertheless, behaviors in the classroom on the part of both teachers and students are not easily changed in marked, systematic, and relatively permanent ways. The classroom itself, for example, has persisted as the primary unit of school organization in spite of a complete absence of evidence that it promotes optimum learning and development.

One factor that makes the possibility of substantial change in educational practice seem remote is the decentralization of control in educational systems. To say that educational practice has not changed much in the past 50 years is not to say that it is homogeneous. Variability, not constancy, is the striking characteristic of educational practice, at least on the face of it, when observational comparisons are made across classrooms and across schools. Even in an educational effort that is subject to more centralized control than any other, Project Headstart, there is very little evidence of consistency in practice from classroom to classroom, whether with regard to teacher behavior, student behavior, group organization, or curriculum (Williams and Stewart, 1966, Boyd, 1966, Temp and Anderson, 1966). The implication of such persistent variability is that orderly, systematic, generalized change in educational practice will be very difficult to promote.

Change is difficult but not impossible to effect. The question is "How can the leverage necessary for change be obtained?" One of the first loci of such leverage that comes to mind is the teacher. It seems that it should be possible to modify teacher training markedly enough to produce dramatic changes in educational practice. But this assumption may be fallacious. For it is probable that since the institutions that train the largest proportion of the nation's teachers are less subject to external pressure for reform, they may be even more resistant to change than the public school systems themselves. Furthermore, as Gagné argues,

The idea that teachers can by themselves bring about the changes required to modernize education is itself part of what needs changing. Teachers cannot possibly do all of

the things they are supposed to do, or that they say they are responsible for doing. They do not have the time, not to mention the capabilities, to design curricula, execute curricula, design instruction, execute instruction, guide individual development, measure individual progress, and consult with parents (Gagné, 1966a, p 49)

If not in the teacher, the leverage for change must be found elsewhere. Whatever the method decided upon, it should permit the incorporation of relevant theory and information regarding cognitive development, insure control over content, procedures, ordering, and organization of instruction, and provide for the evaluation of the outcome of the changes instituted relative to a previously specified set of criteria. Gagné (1966a, p 52) makes a strong case that these things can be achieved where research itself undertakes to "*design, develop and evaluate systems of education*" (For a complete account of recommendations in this vein, the reader is referred to Gagné, 1966a, pp 52-57). Thus hopeful avenues for effecting change can be delineated, but even this does not obviate all of the obstacles in the way of substantial flow of contributions from research and theory in the psychology of cognitive development to educational systems. The issue in this connection is what the psychology of cognitive development has to offer education presently, and how psychology can go about enhancing theory and research to the point where the offering can be substantially increased.

At least two major strategies have been elucidated whereby psychological theory and research may be able to contribute to educational practice. These strategies are markedly divergent in their content and in their implications for *psychological practice*. Consider the antinomies among the following sets of quotations:

The fact that schooling is regarded as an organic process does not mean that it cannot be improved. True enough, our frantic manipulation of the externals of schooling has produced no such improvement. These efforts have tried to produce improvement while ignoring the humble, basic processes by which schooling proceeds. When we honestly turn to a realistic study of these ancient,

earthy and pervasive forces themselves, who knows what improvement may result? (Stephens, 1967, p 14)

Under these circumstances, it seems to me the better part of wisdom to find the good school situations— and engage in close observation and intellectual resonance, then try to recreate such situations and make them more abundant and reproducible, no holds barred (Hawkins, 1967, p 4)

Develop the best pedagogy you can. See how well you can do. Then analyze the nature of what you did that worked. Later on, design hypotheses to determine what you did (Bruner, 1966e, p 113)

The major thrust of the three positions represented by these quotations is that the strategy recommended for improving educational practice is: find and observe schooling in its "best" present form, attempt to understand it, and by understanding it as it is, increase the capability for improving it.

By way of contrast, consider the following quotations from Gagné (1966a):

[E]ducation needs to be newly designed in a very fundamental way—a way which devotes primary attention to the development of the human individual from early years onward (p 51)

If we are satisfied with our present system, the application of knowledge about learning can only refine the preparation of textbooks and the nature of teacher procedures, it cannot be expected to demonstrate improvements of great magnitude. In contrast, the full exploitation of learning knowledge is possible in a newly designed system of education which focusses attention upon the individual learner and his continued development (p 57)

The position implied here is that schooling in its present form, even at its best, is not sufficiently effective to deserve intensive study if the objective is to improve educational practice. Furthermore, this view assumes that knowledge gained in the psychological study of learning and development can contribute to education, whereas the position contained

in the former views is that much available psychological theory and research is grossly inappropriate for application to the problems of schooling

The strategy inherent in the views of Stephens, Hawkins, and Bruner suggests that the path to educational improvement should begin with a theory that accounts for the process and results of present schooling practices. The view enunciated by Gagné and held by many others (see Skinner, 1958, Melton, 1959) suggests that the path begins with a theory that explicates the process of learning itself. The former view asserts that an understanding of the process of schooling will have implications for the practice of educationally relevant psychological research. The latter view implies that what is known about the conditions of learning has application in educational practice, indeed that it dictates a radical reorganization and redesign of educational practice.

This difference of opinion regarding an optimal strategy for relating psychological theory and research to educational practice may be summarized as follows. First, there is little disagreement among psychologists that their craft, in one form or another, has relevance for the solution of educational problems. Second, there is considerable disagreement among psychologists about how to succeed in making positive contributions to educational practice and therefore about whether or not it is even possible. Finally, the dispute indicates that the eventual result of following either strategy is presently unknown and the choice remains, for the time, a matter of personal propensity. From all of these conditions it seems to follow that education and psychology are separated from one another by no more than a membrane but that this membrane may be successfully penetrated only with great effort and care.

The stance that will be assumed here regarding the relevance of a psychology of cognitive development for education and the possibility that contributions will in fact be made to change educational practice differs somewhat from those that have been reviewed thus far. This position is that the question of relevance in its superficial sense should be disposed of quickly. Virtually anything that psychologists do by way of advancing our knowledge of cognitive development will be

relevant to education because of the shared concerns of the two fields. If this were the total of what could be said, its substance would be that everything, and therefore nothing, in the psychology of cognitive development would have relevance for education. Fortunately, more can be said.

In our view, the probability that psychological theory and research will have *effective* relevance for education is conditional upon the way in which investigators proceed. The most favorable starting point is marked by the activity of subjecting some educational objective to psychological analysis. As a first step, this activity has two virtues. First, it produces a formulation of the problem in psychological terms, a necessary prerequisite for any kind of fruitful investigation. Second, it insures that the problem investigated will be germane to education. Too much available psychological research lacks effective educational relevance simply for want of an additional condition or two that would have made it isomorphic with some form of school learning.

After the task of formulating a problem in psychological, that is, researchable, terms has been accomplished, the next step is to subdivide it into components that will yield to the methods of basic experimental research. This may sound quite traditional, differing little from the course followed in the past. Nevertheless, it may be suggested that it does differ and that it differs significantly. It is plausible that the relation between psychology and education has suffered not so much from an overabundance of laboratory research and a paucity of field research, but from the fact that laboratory research, since the early part of the century, increasingly has taken as its objective the understanding of phenomena detected in the laboratory itself rather than in more natural settings. Thus the task of generalization to socially occurring tasks has been made formidable by the lack of fit between laboratory phenomena, on the one hand, and the phenomena of the schoolroom, on the other. The point is not to depreciate this strategy for advancing psychological knowledge but to emphasize the availability of an alternative that has potential both for acquiring basic knowledge and for contributing to education.

The results of basic research performed on

component problems yielded by analyses of school phenomena should have effective relevance for education, such results should provide curriculum makers with guiding information as to the necessary components of optimal curricula. For example, suppose the objective is to assemble the components necessary for an effective curriculum in reading. The psychologist can provide for the curriculum maker an analysis of the skills necessary for attaining reading competence, specifications of an optimal sequence for promoting the acquisition of those skills, specifications of conditions for acquiring each skill most efficiently, information about individual differences relevant to the efficacy of such conditions, as well as means of indexing and then providing for these differences. It is here, in the processes of devising curricula, that direct contributions to educational change can most likely be made. But note that the agent of change is not a psychologist as a psychologist, although he may happen to be one, but as a curriculum maker. The contents of curricular materials, the conditions of their administration to students, and the procedures for monitoring their administration to insure proper implementation—these are prime sources of educational change and the psychology of cognitive development is not at the heart of the process. Psychologists, even those whose objective is the understanding of cognitive development, have no special qualifications for constructing curricula. They are well qualified, however, to produce information that can inform those who do make curricula and it is by performing this function that psychologists can contribute substantially, although indirectly, to educational change.

The potential for contributing to education does not end here, with the discovery of basic information relevant to school phenomena. For rarely will a curriculum embody and exploit properly or fully available psychological information in its first version. It would be equally rare for all the basic psychological information to be valid when generalized to the school setting. Revision should be the rule, revision attendant upon trial, evaluation, and additional basic research provoked by trial and evaluation. Thus the psychologist of cognitive development has additional functions relevant to the development of curricula. His expertise and understanding are needed for

proper evaluation of the effects of a curriculum upon the cognitive capabilities of the students involved. These qualities are also needed for the solution, probably through additional laboratory research, of puzzles presented by the results of curricular efforts, puzzles relevant to both the advancement of basic psychological theory and the effecting of salutary educational change. For example, the method of learning sets is known to be a powerful procedure for establishing discrimination skills in relation to laboratory tasks. When applied to the acquisition of letter discrimination as a part of early reading training, however, it might prove ineffective. Thus might an explanatory puzzle be posed for psychological theory and a practical obstacle be placed in the way of educational improvement.

Note also that this view of the possible growth of relationships between cognitive development and education requires an alliance among psychologists, curriculum makers, and probably teachers and other schoolmen as well. Such an alliance need not be constant but it is crucial at two points. The first is that at which the curriculum maker attempts to map psychological information into curricular materials and procedures—at this point the effective communication of his work is mainly the psychologist's task. Second, the processes of evaluation and subsequent revision require a well-functioning liaison between these disparate agents, so that the sense of evaluation can be made clear to all concerned and so that the implications of evaluative results can be persuasively explicated.

Thus far in the discussion, "psychology" and "the study of cognitive development" have been used rather indiscriminately, almost as if the referents of the terms were identical. Obviously this is not the case and before proceeding further, it is well to clarify the extent and the limits of the domain with which we are concerned. As we regard education, our concern shall be with psychological theory and research in the area of cognitive development. Consistent with this avowed purpose, little consideration will be given to matters of personality growth and development, physical growth and development, or group processes and organization. We shall admit within our view topics such as learning, problem-solving, concept attainment, cognitive

style, individual differences in intellectual behavior, perceptual development, reasoning, psycholinguistics, attention, and even measurement and evaluation. Our principal focus shall be on the changes and constancies in these psychological functions and attributes as the human organism grows and our aim will be to relate this focus to the problems of schooling and the needs of educational practice.

The succeeding discussion is organized in terms of educational needs on the one hand and corresponding resources in the psychology of cognitive development on the other. The educational needs emphasized are those implied by the educational problems already noted. The assumption here is that as solutions to the problems are obtained, the needs will be met.

TOWARD A RATIONALE FOR EDUCATIONAL PRACTICE

At a very general level, schoolmen need a widely acceptable rationale of educational practice. Such a rationale would be comprised of many components, each of which should serve to satisfy relatively more specific educational needs underlying the problems with which schoolmen must deal. Some of these components could be furnished with contributions from the psychological study of cognitive development and it is to these components that we now turn our attention.

A Theory of Educational Development. Even though the term "theory" interpreted in its strict sense may be inappropriate in this context, it will be used to refer to a set of assumptions about the nature of the processes whereby students come to be educated and about the kinds of conditions that affect those processes. Substantial contributions to this component may come from selective revisions of theories of cognitive development that have been made and are being made by psychologists.

Criteria of Successful Education. An adequate rationale of educational practice ought also to specify the objectives or goals of the educational process. The broad goals of education must, of course, be determined by a number of agencies in the society, not by psychologists alone. Nevertheless, the work of psychologists in the area of cognitive develop-

ment can contribute to efforts in this direction by analyzing the criteria into psychological components and by providing behavioral translations of these components. In this connection we are concerned with rather broad capabilities, such as that of intelligent behavior, or creative thinking, rather than with narrower capabilities such as those that might be specified as the proper outcome of the completion of courses in secondary-school mathematics.

Curricula Leading to Criterial Attainment

Once the criteria of a successful education are specified it becomes necessary to consider the means by which students can be guided to them. In educational terms such a specification involves the description of curricula. In psychological terms, this task involves describing the capabilities necessary for the attainment of the criteria and the order of their acquisition or emergence in the developmental course of the student. The task cannot, however, end here, for formal education is interventionist in nature, not observational. Thus the psychologist's role may be larger than that of describing developmental sequences of capabilities. It may include as well the function of specifying the conditions and sequences of learning that are most fruitful at the various developmental statuses. These two functions of the psychologist's role can be brought directly to bear on educational practice in his efforts to collaborate in the construction and revision of curricular materials.

Prerequisites for Curricular Educability.

Another major educational need is the need for a specification of the prerequisites a student must have in his possession in order to make successful use of succeeding curricula. Statements of these prerequisites must be made separately for each of the major educational junctures. Perhaps the most important of these junctures is at the very beginning of formal schooling and, fortunately, the resources in the psychology of cognitive development are probably richest with respect to just this juncture. Other junctures can be identified but for the moment it will suffice to think in terms of the succession of grade level interchanges that form the major demarcations of schooling. In each case the question to be answered is: What are the capabilities that are assumed to be in the student's reper-

tory by the curricula that will next be imposed on him? Resources relevant to this question that are presently available in psychological theory and research are of two kinds. First, they consist of descriptions of the capabilities that a child brings to any given educational juncture by virtue of his developmental status. Second, resources are to be found in analytic studies of the tasks that underlie school curricula. The results of such studies yield specifications of capabilities necessary for the successful accomplishment of these tasks. Thus psychological work on cognitive development can provide critical information about the extent to which the capabilities a child brings to a curriculum mesh with the prerequisites dictated by the nature of the curriculum.

Indexing the Possession of Prerequisites

Another component of an adequate educational rationale is the development of means for determining whether or not, or to what degree, a prerequisite is in the repertory of a student. It is one thing to describe the capabilities that are required by immediately succeeding tasks and another to construct means for indexing the student's possession of those capabilities. One of the glaring weaknesses in available methods of assessing intellectual status is their inability to reveal what has been learned in direct relation to (1) curricula completed and to (2) curricula scheduled to follow immediately. Help for this condition is probably not to be found in traditional work on problems of psychological assessment but instead in research on cognitive development. That is to say, the customary approach to the measurement of individual differences assesses the status of an individual by comparing his performance with that of other comparable individuals. So that, for example, a first-grade child may be judged to be progressing adequately if his performance on a reading achievement test is equivalent to the average performance of all other first-grade children. Unfortunately, judgments made in this fashion may be entirely irrelevant to the questions whether the child has learned what was intended in the first grade and whether he possesses the prerequisite capabilities for successful performance in the second grade. Accordingly, a different measurement model is required for application in education, and such a model

may be found in the practice of psychologists who conduct experimental research on cognitive development. In an experiment on learning, for example, a subject's performance is measured by comparing it with a criterion rather than with the performance of other subjects in the experiment. The criterion in these cases is simply a behavioral translation of what the subject was instructed to learn, such as making response *A* to sentences in the active voice and response *B* to sentences in the passive. It is precisely this kind of measurement that is necessary for adequate indexing of the possession of curricular prerequisites.

Facilitating the Acquisition or Emergence of Prerequisites

If the need for adequate assessment methods is satisfied, it will still remain to construct procedures for speeding up the processes whereby prerequisites emerge. At one level, the psychology of cognitive development cannot presently supply unequivocal answers to this problem since such would presuppose the resolution of a corresponding issue in psychological theory itself. This issue, of course, is to what extent experience can alter the pace of maturation. But as empirical work continues toward a resolution of this abiding dispute, considerable information is produced. And this information largely concerns methods for facilitating the acquisition of capabilities whose emergence is a function of experience.

Providing for Individual Differences Inevitably, individuals differ. For educators, the pervasive character of such differences creates an enormously important brace of needs. The first is for reliable and fruitful methods of identifying the nature of these differences in educationally useful terms. The second of the needs is for effective methods of dealing with such differences once they are identified. Although the psychological study of individual differences in intellectual capabilities has a relatively long history, help for education is to be found not so much here as in the field of our present focus. Even though the psychology of cognitive development is comparatively young, it is beginning to produce important ideas about assessing and providing for individual differences that may contribute substantially to fulfilling this signal educational need.

CONTRIBUTIONS TO A THEORY OF EDUCATIONAL DEVELOPMENT

Two rather distinct kinds of efforts to re-work psychological theories in the interest of enhancing their relevance for education may be distinguished. The first effort emphasizes maturational processes, drawing heavily upon the work of Piaget (1952). One of the principal versions of this kind of theory has been promulgated by Bruner (1966a, 1966b, 1966c, 1966d). The second effort emphasizes learning over maturational processes, one of its major exponents is Gagné (1965a, 1965b, 1965c, 1966a, 1966b, 1968).

In thinking about theories of cognitive development while keeping educational purposes in mind, it is tempting to set forth alternative conceptions, that is, ones that are opposing and mutually exclusive. An apparent beginning in this direction appears in the present organization of the topic into two separate sections pitting a maturational emphasis against a learning emphasis. Let it be clear, however, that here this adversary approach is more appearance than substance. With regard to educational purposes, the viewpoints are often not at all mutually exclusive. Indeed, at some points they are complementary. And, as we shall see, the two types of theory, even when taken together, leave a number of important gaps for a theory of educational development.

A word is in order about the strategy used here of concentrating attention on single representatives of major theoretical positions. The choice is not based on the mistaken belief that these are the only exemplars available in each category nor upon the judgment that they will necessarily prove to be the most fruitful. Rather, the specific expressions of the two viewpoints were selected because their authors, to a somewhat greater extent than others, have concerned themselves not only with the construction of a theoretical position in the psychological domain but also with drawing implications for and making contributions to educational theory and practice. In consequence these theoretical viewpoints are especially well-suited for examination with respect to their relevance for education.

A Maturational Emphasis

A schoolman may be principally concerned either with what it is a child learns and how well he learns it or with what functions the child will be capable of performing at the end of some learning episode. In fact, the schoolman is properly concerned with both, with the extent to which students master set theory and with the extent to which they can engage in effective mathematical reasoning. Nevertheless, there are two different emphases here and they emerge in parallel fashion when we examine theories of cognitive development. In a theory that partakes more of a maturational than a learning viewpoint, the emphasis is on the relatively longer term and more general functional capabilities of the maturing organism and on the structures that underlie them.

What Bruner (1966c) has called *instrumental conceptualism* is representative of a theoretical viewpoint having a maturational emphasis. Characterizing the theory, he notes

In brief, it is a view that is organized around two central tenets concerning the nature of knowing. The first is that our knowledge of the world is based on a constructed model of reality, a model that can only partially and intermittently be tested against input. [T]he second is that our models develop as a function of the uses to which they have been put first by the culture and then by any of its members who must bend knowledge to their own uses (pp. 320-321).

In more conventional language, instrumental conceptualism holds that what is known is constrained and determined by characteristics of the organism (from within) and by characteristics of the environment, especially the cultural environment (from without), in which the organism grows. Innate propensities are granted by the theory and, in fact, justify the importance given by it to the tenet that reality is "constructed." For in this view, human beings exhibit far more competence than would be expected on the basis of the experiences they have had. The best known example in this regard is linguistic competence. It can be shown that adults have the capacity to construct an infinite number of different sentences, all of which may be gram-

mathematical. Clearly, this capability cannot be accounted for entirely by what an individual hears, some mechanism for generating sentences must be posited. Furthermore, it turns out that any mechanism adequate to account for linguistic competence must have certain properties that cannot be acquired solely from the experiences that human beings have. Accordingly, it is necessary to assume that human beings have a propensity for the development of certain linguistic mechanisms and that the particular one that does develop in an individual depends upon the specific language he hears. Thus the linguistic environment determines which of several inherent mechanisms is activated, but the environment does not account for the formal properties of the mechanism. Similarly, when this view is extended to knowledge acquisition and intellectual capabilities in general, it implies that the organism must build its reality on the basis of relatively little information and such building involves the modification of inherent capacities. The occasions for and the possible forms of modification are both provided and limited by the environment.

Central to this theory of cognitive development is the notion of *representation*. The *media* and *objectives* of representation, indeed, form both the criteria of the extent of development and the major content of what has developed in an organism to any particular point in time.

The concern with representation is a concern with the ways in which the organism's experience with its world are encoded and stored. Three media of representation are distinguished: action (enactive representation), image (ikonic representation), and symbol (symbolic representation). Each one of these media of representation, according to Bruner, can be used in the service of the objectives of symbolic manipulation, image organization, and motor action. Note that each mode of representation is versatile in this sense, it can be recruited in the service of objectives that seem more akin to one of the other modes. Symbolic representation, for example, can be useful in the organization of action, as when a paragraph specifies the steps to be taken and the order in which to take them to accomplish such an objective as finding one's way to the nearest gas station.

Despite the each-to-all relationships obtain-

ing between media and objectives of representation, the three media are construed as landmarks of development. Such a construction can be placed upon the media by virtue of the sequence of their inception in the cognitive activities of the child, it is supposed that the enactive mode emerges first, followed by the ikonic, followed, in turn, by the symbolic. It must be noted in this connection that the theory is not a simple one. It does not refer to an enactive stage nor to an ikonic or a representational stage. It does not contend that enactive representation is *replaced by* ikonic representation, each kind of representation can be and is used at all ages after its inception so that an older adolescent in this culture would be expected to exhibit all three kinds of representation. Finally, the theory is not simple in the sense that it assumes the three modes of representation to be universal in terms of the forms in which they develop, that is, constant across cultures. On the contrary, the viewpoint explicitly contains a description of at least one culture in which it appears that some possible uses of the symbolic representational mode never emerge (Bruner, 1966b).

The latter point illustrates the important place assigned to the cultural environment in instrumental conceptualism, especially as regards the determination of the nature of cognitive processes and structures. If the culture does not in some sense require the emergence of some of the forms of a mode of representation, especially in the case of the symbolic mode, those forms are not likely to develop. If the culture does not make available certain conceptual tools, they will not be acquired.

Thus in instrumental conceptualism some of the prime conditions for cognitive development are environmental, these conditions are to be found both in the demands the environment makes and in the opportunities it offers. At least two other sources of developmental propulsion are distinguished in the theory. The first is curiosity and its attendant competence motive, which flourish in the presence of specifiable kinds of environmental stimulation. The second additional source of developmental propulsion is also internal, a kind of equilibrium-disequilibrium mechanism but in a novel form that is well-suited to the representational emphasis of the theory. This source of propulsion is occasioned by conflict be-

tween representational media. The contention (Bruner, 1966a, p. 11) is that when one mode of representation contradicts another, cognitive growth ensues, as when "how one must act overtly and how the world appears" are not consistent.

Given this much of the theory, it is possible to infer that development from the viewpoint of instrumental conceptualism will be characterized by plateaus and relatively abrupt changes. These can be seen as such, however, only when close observations are made on the same children over time with regard to their performance on the same task. Discontinuities would not be expected to appear when performances are averaged across children, or when a child's performances are averaged across tasks, since the inception of a representational mode is not tied directly to a particular chronological age for all children, nor does it emerge at the same time in connection with all kinds of intellectual functions. The development of a new mode of representation will permit a child to perform in a way that is markedly different from what he could have done previously on the same task.

Two further features of the theory of instrumental conceptualism need emphasis before we turn to a consideration of its potential for contributing to a theory of educational development. The first is its explicit recognition of the nature of the organism as a determinant of the forms and boundary conditions of cognitive development. This feature of the theory marks its nativistic propensity but as we shall see shortly, the sort of nativism involved is neither naive nor traditional. This characteristic of the theory is illustrated in the following passage:

To sum up our discussion of symbolic representation, symbolic activity stems from some primitive or protosymbolic system that is species-specific to man. This system becomes specialized in expression in various domains of the life of a human being: in language, in tool-using, in various atemporally organized and skilled forms of serial behavior, and in the organization of experience itself. We have suggested some minimum properties of such a symbolic system: categoriality, hierarchy, prediction, causation, and modification. We have suggested that *any* symbolic activity,

and especially language, is logically and empirically unthinkable without these properties.

In view of the autonomy of the syntactic sphere from other modes of operating and of its partial disjunction from the semantic sphere, one is strongly tempted to give credence to the insistence of various modern writers on linguistics that language is an innate pattern, based on innate "ideas" that are gradually differentiated into the rules of grammar (McNeill, 1966, Chomsky, 1965, Katz, 1965) (Bruner, 1966b, pp. 47-48).

The material in this quotation represents fairly accurately the role assigned to innate factors in the theory. Further comment, however, is needed to clarify Bruner's conception of the relation between language and other forms of symbolic representation and activity.

In spite of the admission that language constitutes a special case, Bruner nevertheless argues (1) that it evolves out of the same organismic givens as do other forms of symbolic activity, and (2) that it is, therefore, not the sole determinant of other forms of intellectual activity. On the contrary, the contention is that a necessary precondition for the development of linguistic control of other kinds of activity is the modification of the representational processes originally underlying such activity so that they are isomorphic with the structure of symbolic representation in language. Only after such preparation is complete can control of the activity be shifted to the language system. More must be said about this matter later in reference to its implications for educational practice.

The sort of nativism that characterizes the theory does not have the implication that experience is irrelevant to cognitive development. Indeed a second feature of the theory tempers its nativistic stance. As already noted, considerable importance is assigned to the culture in determining the specific nature of cognitive processing that develops in children. But even more specifically and explicitly, the theory assigns a substantial role in cognitive development to the school and to the tutor-tutee dialogue as represented by relationships between teachers and students and by those between parents and children. This kind of contention takes such a strong form that the theory appears to assert the *necessity* of such

dialogues for the development of pervasive use of symbolic forms of representation along with all the intellectual potency they entail

We turn now from instrumental conceptualism as a psychological theory to consider its implications for educational theory and practice. We will also consider whether these implications can be traced back to the developmental theory to indicate its potential for making contributions to education. In seeking answers to these questions we rely heavily on a book by Bruner (1966d), *Toward a Theory of Instruction*, which is informed with the psychological version of the theory.

For Bruner, "the heart of the educational process consists of providing aids and dialogues for translating experience into more powerful systems of notation and ordering" (Bruner, 1966d, p. 21). Thus the development of the various modes of representation is as central in educational development as in intellectual development in general.

As Bruner notes, a theory of instruction may be distinguished from a theory of learning or a theory of development in that the first is necessarily a "prescriptive" theory, whereas the latter are essentially "descriptive." A theory of instruction, for example, ought to specify not only how learning and development normally proceed but how they can be made optimal. Four features of a theory of instruction are distinguished. The first concerns the specification of conditions that are necessary and sufficient for producing in the child an affection and a propensity for engaging in learning. Second, the theory should specify the optimal way in which what is to be learned ought to be organized relative to the capabilities of the learner. The third feature of a theory of instruction concerns the optimal sequencing of what the child is expected to learn. Fourth, a theory of instruction should contain specifications of the kinds and timing of reinforcements to be delivered to the learner.

The details of these features are of interest since it is in them that we can see the inferences that may be drawn from the theory of instrumental conceptualism for educational theory and practice. First, consider the matter of engendering a positive regard for, and a tendency to engage in learning. Bruner tends to reduce this feature of the theory to the task of activating, maintaining, and directing

the exploration of alternatives on the part of the child. *Activation* is equated with the arousal of curiosity. This, it is contended, can best be done by presenting tasks that are characterized by optimal uncertainty. The hand of the instructor is important here in the selection of appropriate tasks. It is important as well for *maintaining* exploration since this depends upon insuring that the activity is more rewarding than punishing. The *direction* of exploration is held to be determined by two things: information about the goal to be achieved, and information about the relevance of one's way of proceeding. Both of these things can be provided by the instructor.

An obvious addition to this list of conditions relevant to exploration is concerned again with activation and maintenance and is suggested directly by instrumental conceptualism. As we noted, the theory holds that one of the main propulsions to problem-solving activity is conflict between two modes of representing the same knowledge. It is an obvious inference that the selection of tasks should be made with such conflict as a criterion and that the maintenance of exploration ought to be aided when the instructor sees to it that the conflict remains salient during the course of the learner's activity. For example, if the aim is to teach Archimedes' principle of flotation, exploration might be maintained by presenting to the student a series of instances of "light" objects that sink in water and "heavy" objects that float.

With regard to the *organization* of knowledge to be acquired, Bruner restates the widely disseminated notion that "Any idea or problem or body of knowledge can be presented in a form simple enough so that any particular learner can understand it in a recognizable form" (Bruner, 1966d, p. 44). Three variables are distinguished to define the form in which knowledge is presented. The first of these, familiar by now, is the mode of representation in which the knowledge is communicated. The other two variables are the economy and the effective power of the organization adopted. The contention is that any sort of knowledge can be represented initially in each of the three representational modes, the one chosen depending upon the child's presenting capabilities, that is, the capabilities already in the child's possession when

he begins work in an instructional sequence Economy of presentation refers to the information load necessary for comprehension of a subject matter the less the load, the easier the comprehension A prescription is implied here find the most economical form consistent with the inherent nature of the material to be learned and present materials in that form The power of a particular way of organizing knowledge apparently refers to whether or not it permits the learner to make maximal use of knowledge in solving problems as yet unencountered, a form of transfer

Before considering the problem of sequencing materials, it is important to pause and examine more carefully the notion that any idea can be acquired by any learner at any age On its face, the assertion seems to give the lie to an interpretation of instrumental conceptualism as a theory having a maturational emphasis For this contention seems to require the assumption that prior growth is never necessary for the acquisition of any given kind of knowledge But a more careful examination of the assertion reveals that it is consistent with a maturational view, although not with a passive, *laissez-faire* version of such a view Notice the conditional phrase, "knowledge can be presented in a form *simple enough*" The form of presentation must fit the status of the organism The theory does not contend that any child of any age can, at that age, be taught any particular knowledge, even in its most complex form, by simply sequencing the material properly Rather it contends that the instructor can formulate any knowledge in a form consistent with the developmental level of the child, a contention that may leave many an instructor both flattered and disbelieving

The *sequencing* of materials involves decisions made in accord with criteria that are multiply determined The ground rule suggested by instrumental conceptualism is that in terms of modes of representation, a task should first be presented, and the learner should first be engaged in the task enactively, then ikonically, and finally symbolically This inference follows from three properties of the parent theory first, that this sequence of modes is the ontogenetic sequence for most children, second, that all modes persist after they have initially emerged, thereby providing alternative ways of representing almost

any subject matter, and, third, that the earlier modes provide a second line of attack when the symbolic mode, for one reason or another, fails Another reason for the recommendation that instruction should begin by presenting knowledge enactively, then ikonically, and then presenting it symbolically is partially obscured It seems to be presumed that the only fruitful route to the symbolic representation of any knowledge is through prior enactive and ikonic representations If true, this position has important implications for educational practice It suggests, for example, that verbal modes of presenting material on the part of the instructor and of responding to it on the part of the student are much over-emphasized in schooling Furthermore, it suggests that the concern of many educators and psychologists with the alleged language deficiencies of lower-SES children may be excessive The excess, however, is not a general one Bruner would surely agree that a well functioning symbolic system such as language is necessary for symbolic representation But the possession of such a system is not sufficient Thus the implication is that lower-SES children need training in enactive and ikonic representation as well as in symbolic representation of the material to be learned

Despite its interesting implications, however, the assertion that all kinds of knowledge should first be presented to students enactively must be viewed with considerable skepticism Some kinds of knowledge may not lend themselves to enactive representation Consider, for example, the difficulty of presenting a concept such as that of an imaginary number enactively In the case of knowledge of this kind, the principal task of instructional design may involve questions of the optimal sequence of presentation *within* the symbolic mode rather than *across* the three modes of representation What should be the sequence of presenting subsidiary knowledge symbolically in order to facilitate the student's eventual acquisition of the concept of imaginary numbers? The theory offers little assistance in arriving at answers to this kind of question regarding the problem of sequencing

The timing and nature of effective reinforcements is judged to be crucial for their success in aiding learning Optimally, feedback should occur when the learner is judging the product of his activity against the standard

of the goal that has been presented to him. The form of reinforcement, taken now to mean informational feedback, must be consistent in representational mode with the mode being used by the learner. Otherwise the learner's task will be made more difficult rather than facilitated by the reinforcement. Furthermore, the reinforcement must itself contain information as to whether or not the learner's activity is advancing him toward his goal.

Clearly, all of these features of a theory of instruction are relevant to the activities of a variety of schoolmen, those concerned with the construction of educational materials, those responsible for curriculum planning, and those directly responsible for instruction, namely, teachers. Indeed, in the theory of instruction that follows from instrumental conceptualism, the role of the teacher is especially crucial in two respects. First, the teacher is a source of knowledge that the student does not possess. In comparison with other sources of knowledge, such as books, for example, the teacher is unique in that he himself represents the student's goal of having acquired the knowledge in question. Secondly, the teacher is crucial insofar as he can modify his activity as a source of knowledge in direct consequence of the student's successes and failures in the course of acquisition. Bruner says, for example, "*Intellectual development depends upon a systematic and contingent interaction between a tutor and a learner, the tutor already being equipped with a wide range of previously invented techniques that he teaches the child*" (Bruner, 1966d, p. 6). Perhaps it is a misconception issuing from a too literal reading of this theory that the teacher, as this position is usually understood, occupies a crucial role. For *teacher* can refer to any method for availing the child of knowledge possessed by others, including personal interaction with adults. Nevertheless, there is running throughout Bruner's explication of instrumental conceptualism and of its implications for a theory of instruction a respect for and an acceptance of existing modes of organization of the school. Not so for the existing practices of presenting knowledge to students, however. In this area, innovation, change, experimentation, all are recommended.

The contribution of instrumental conceptualism to a theory of educational develop-

ment cannot be properly evaluated in the absence of some attention to its specific application in education. Bruner (1966d, pp. 54-72, Bruner and Kenney, 1965) describes an effort to teach quadratics to four 8-year-old children. The account is remarkable in two regards. First, it succeeds in illustrating the four propounded features of an instructional theory. A predisposition for learning was found in the children, further activated through the introduction of novelty, maintained by alterations of the materials and problems presented, and directed in truly ingenious ways by the two teachers. With respect to organization and sequencing of presentation, the practices followed were clearly consistent with the theory. The children were initially engaged in enactive behaviors. For example, they were presented with a square block of wood and were asked to make a succession of larger squares by physically adding other pieces of wood of constant size to the original one. It was assumed that the children represented the outcomes (appearance of the new squares) to themselves iconically through imagery. Symbolic representation was initiated by encouraging the children to keep a written record of the numbers of pieces of wood added to each square in the course of making the next larger one. The economy of the underlying structure was given in the notation used for record-keeping, a notation provided by the teachers. The power of the structure was demonstrated when the children were encouraged to transfer their newly acquired skills, as well as the attendant notation, for square-building to the task of balancing a beam. Because of the materials used (the squares and the beam balance) reinforcement was contingent upon the child's own actions, came immediately, and was directly available in the child's product rather than being mediated by the teacher. Thus in these ways the theory did make palpable contribution to this limited bit of educational practice, and impressive practice it was.

The second remarkable aspect of this instructional effort is that very little of it seems to be directly and explicitly implied by the theory. This may mean that the educational utility of the theory is severely limited. The point is that this theory of development cannot make substantial contributions to edu-

cational practice if it can be used very successfully only by extraordinarily ingenious and gifted schoolmen. Consider, for example, that aspect of quadratics instruction that most clearly reflects the influence of the theory—the sequencing of modes of representation. To be sure, the sequence was initiated in an enactive mode and this was eventually followed by guided transitions to ikonic and symbolic modes. But the particular expressions of these modes appear to be entirely *ad hoc* with respect to theory. Moreover, there are no “instructions to schoolmen” as to procedures for deciding precisely what expression to give to each of the modes in constructing a sequence of instruction.

It might properly be said in response to this reservation about the utility of the theory for education that it is misdirected. After all, the author of the theory explicitly states that it is in the early stages of formation and that considerable work of the sort described in connection with the sequence of quadratics instruction must be done before applicability can be demonstrated one way or another. But the point must still be emphasized that for a theory of cognitive development to effect changes in education, it must contain means for its implementation. To put the matter another way, a theory of instruction must give attention to instructing schoolmen in its use. One of the advantages of a theory is that it makes public and explicit what would ordinarily be relatively private and implicit. One way of accomplishing the aim of implementation is largely to bypass the teacher and to guide the production of self-contained instructional sequences that leave little room for instructor intervention except, perhaps, in matters of administration. But in the theory emanating from instrumental conceptualism this seems an inappropriate strategy since so much is ascribed to the functions of the teacher. Thus even though the goal has not been achieved, it must remain salient, for too much can be lost in the translation of theory into practice when the success of the translation depends critically on the translator and his individual talent.

To sum up this review of a theory of cognitive development that emphasizes maturation, here is an annotated list of educationally relevant positions that emanate from instrumental conceptualism.

1 The heart of intellectual development is the emergence of three major systems of representation, the enactive, the ikonic, and the symbolic. Ontogenetically, these systems emerge in the order given but after their initial appearance all continue to operate concurrently. One or the other system may be especially relevant to a given kind of knowledge and in instruction this fact must be specifically taken into account. In many instructional sequences, the best route starts with the enactive mode and recapitulates ontogenetic development in teaching the subject matter.

2 Relationships among the three modes of representation must be prepared. If, for example, the goal of an instructional sequence is to permit the student to represent material to himself symbolically, the structure of the symbolic representation must be specified. Then the structure of representation in the prerequisite enactive and ikonic modes should be made isomorphic with that envisioned for the symbolic mode. Only after this is accomplished should translation be attempted from one mode to the other. To give an example of an implication following from this position, it would suggest that the culturally disadvantaged child should be led to reorganize his knowledge in existing enactive and ikonic modes *before* any attempt is made to force that knowledge prematurely into a symbolic mode of representation.

3 Readiness is a matter of prior learning and development and need not be awaited. Although the theory is adamant on this point, it is not altogether clear. That is to say, the issue is complicated. The extent to which maturational factors limit what can be learned appears to be determined only by the ingenuity of the schoolman in properly representing the subject matter to the student. Yet it is also suggested in the theory that some growth is required, in addition to instructional experiences before final representations of an area of knowledge can take, say, an optimal symbolic form. In this light it is unclear what educators should do about the notorious problem of readiness.

4 In addition to its emphasis on a few powerful innate and maturational factors, the theory relies heavily on the role of culture as a determinant of the nature of intellectual development. In its praiseworthy dissatisfaction

tion with the simple statement that culture is important, the theory goes on to specify the agency by which culture determines cognitive development the tutor-tutee relationship. The teacher's role, whether it is performed by a formal teacher or informally by a parent or some other adult, is critical for making available to the child the tools of cognition, for instigating and maintaining learning, for structuring and sequencing knowledge, and for arranging materials and the environment so that they deliver informative reinforcement of appropriate kinds at appropriate times. Thus a crucial implication of the theory is that the preparation of teachers for providing successful instruction is prerequisite for optimal educational development.

5 Individual differences are explicitly expected to emerge in connection with any one of the four functions of the teacher listed. The implication drawn from this is that a variety of means must be found to the same ends, depending on the presenting characteristics of the child. The theory, however, does not discuss at any great length the problems presented for education by individual differences nor does it make sufficient proviso for their solution.

6 Finally, as it stands presently, the theory is stated at such a high level of generality that the implementation of its implications in educational practice is left almost entirely to the ingenuity of the schoolman, whatever his capacity. Presently it can make contact with educational practice only in the hands of brilliant and inventive practitioners. Its relevance for education is well-substantiated, its contribution to education is almost entirely potential, and the likelihood that it will truly effect improvement is indeterminate.

A Learning Emphasis

Any number of theorists among psychologists could be chosen to represent a learning emphasis in connection with the topic of cognitive development and education. Gibson, Jensen, Kendler, Osgood, Skinner, Staats, or Underwood, to name some. Although the views of these psychologists will be referred to later, principal attention will be given here to Gagné's explication of a theory of cognitive development with a learning emphasis (Gagné 1965a, 1965b, 1965c, 1966a, 1967, 1968). The reason for the choice is a simple one,

Gagné (1965a, 1965b, 1965c, 1966a, 1967) has made the most thoroughgoing attempt to translate a learning approach into a view of development that speaks directly to educational issues.

Gagné (1968) distinguishes between learning and development principally in terms of the time span occupied by the changes in capabilities of an organism. Both learning and development are defined as changes in capabilities. Both learning and development are contrasted with growth and maturation as principles for explaining changes over time. While admitting that development must be viewed as a joint function of learning and growth, Gagné's emphasis is clearly upon learning.

If growth is the dominant theme, educational events are designed to wait until the child is ready for learning. In contrast, if learning is a dominant emphasis, the years are to be filled with systematically planned events of learning, and there is virtually no waiting except for the time required to bring about such changes (Gagné, 1968).

Although Gagné's emphasis is upon learning processes and although it starts with learning conceived in an associationistic framework, his approach departs in crucial ways from a strict connectionist model. The theory is descriptively called a *cumulative learning* model and its major components are the traditional ones of learning, memory, and transfer. It differs from other learning models of development, however, in its identification of what it is that can be learned.

In a traditional model *connections* between specific stimuli and responses are the entire content of learning, regardless of the complexity of the connections required to account for behaviors. But in the cumulative learning model, it is allowed, indeed it is firmly asserted, that much more complex forms of content, such as rules and principles, are learned. This being the case, the question is what distinguishes the cumulative learning model from more cognitively oriented theories such as that of Bruner (1964, 1965, 1966a, 1966b) or Piaget (see Flavell, 1963). The difference is in the detailed specifications of prerequisite learnings that the cumulative model requires for the occurrence of rule or principle

learning. Thus cumulative learning theory contends that acquisition processes are hierarchically organized and that the various processes are distinguished from one another in terms of the characteristics of the performances by which each is expressed and in terms of the internal and external conditions necessary for their occurrence.

The most complete exposition of the hierarchical model itself is given in *Conditions of Learning* (Gagné, 1965a). Seven varieties of learning are distinguished: S-R connections (motor acts), *motor chains*, *verbal chains*, *multiple discriminations*, *concepts*, *principles*, and *higher-order principles or strategies*.

The simple fact that learning is subdivided in this manner has the consequence of asserting that all learning processes are *not* the same. Each of the varieties of learning is identified in terms of the characteristics of

its attendant *performances*, necessary *internal conditions*, and necessary *external conditions*. Later we shall see how each of these means of identifying a variety of learning has implications for education. But for now examine the following summary of the matter taken from Gagné (1967, p. 301).

Each one of the internal conditions of learning forms a prerequisite capability for learning of the next higher variety. Thus

1 The possession of *stimulus-response* connections is prerequisite to the learning of

2 *chains*, whether motor or verbal. These (or in the simplest case, S-R connections) are prerequisite to the learning of

3 *multiple discriminations*, which are prerequisite to the learning of

Table 1 Summary of Conditions Considered Necessary for Seven Kinds of Learning

Performance Established by Learning	Internal (learner) Conditions	External Conditions
Specific responding	Certain learned and innate capabilities	Presentation of stimulus under conditions commanding <i>attention</i> , occurrence of a response <i>contiguous</i> in time, <i>reinforcement</i>
Chaining		
Motor	Previously learned individual connections	Presenting a <i>sequence</i> of external cues, effecting a sequence of specific responses <i>contiguous</i> in time, repetition to achieve selection of response-produced stimuli
Verbal	Previously learned individual connections, including implicit "coding" connections	Presenting a <i>sequence</i> of external verbal cues, effecting a sequence of verbal responses <i>contiguous</i> in time
Multiple discrimination	Previously learned chains, motor or verbal	Practice providing <i>contrast of correct and incorrect stimuli</i>
Classifying	Previously learned multiple discriminations	Reinstating discriminated response chain contiguously with a <i>variety of stimuli</i> differing in appearance, but belonging to a single class
Rule using	Previously learned concepts	Using external cues (usually verbal), effecting the recall of previously learned concepts contiguously in a suitable sequence, specific applications of the rule
Problem solving	Previously learned rules	Self-arousal and selection of previously learned rules to effect a novel combination

4 *concepts*, which are prerequisite to the learning of

5 *principles*, which are prerequisite to the learning of

6 *high-order principles* including *strategies* (Gagné, 1966a, p. 41)

Clearly, learning is conceived to be organized hierarchically so that complex forms of learning are dependent upon prior, simpler forms.

Although it may not be so clear, it is equally a characteristic of this theory that the more complex forms of learning are not simply a collocation of the learning of many, many connections. The learning of a rule like "Alleviation of the conditions of an oppressed social group produces revolutionary behavior in members of that group," is not a matter of learning the connections between the individual words in the rule. But the acquisition of such a rule does presuppose the prior learning of the concepts involved, of the multiple discriminations necessary for the learning of these concepts, of the chains necessary for the learning of the discriminations, and of the connections necessary for the learning of the chains.

An additional specification of the model deserves emphasis. The acquisition of a higher-level capability, such as a rule, depends not only upon the prior acquisition of lower-level capabilities but also upon the retention of those previous learnings. That is to say, even if all of the learnings prerequisite to the learning of a rule can be shown to have been accomplished, this will not suffice unless these previous learnings can be recalled when the rule is to be learned. This assertion fits well with recent evidence concerning the conditions necessary for demonstrating a facilitory effect of mediational conditions in verbal learning tasks (Horton and Wiley, 1967). It has been shown that unless a mediate term in a supposed verbal chain can be recalled at the time the two ends of the chain are being learned, its previous acquisition will not facilitate the new learning. Later we shall examine the pronounced implications that this facet of the cumulative learning model has for educational practice.

With this brief summary of Gagné's explanation of the varieties and conditions of learning, let us turn to a discussion of the significance of the term *cumulative* in the learn-

ing model. In part, this discussion has already begun because some portion of the meaning of cumulative is given in the specification that the learning of capabilities is hierarchically organized and that earlier learnings must be recalled in order for newer ones to proceed successfully. In this sense learning may be said to be cumulative, but it is also held to be cumulative in another way having to do with transfer and generalization.

Cumulative learning theory needs a transfer component if it is to be at all persuasive. Consider, for example, the inconceivably large number of hierarchies of learning that would have to be specified to outfit a growing human being with all of the principles that most adults have at their disposal. A lifetime would probably not be long enough for each individual to acquire such a vast set of rules if it is held that in the case of every rule capability he must traverse anew the relevant hierarchy from its base to its apex. Without some sort of transfer mechanism, the same property that gives cumulative learning theory its appeal—that is, its intent to specify in detail the conditions necessary for the acquisition of a complex capability,—also limits it to virtual inapplicability to human intellectual development.

Fortunately, the model does contain a transfer component. Indeed, Gagné says, "cumulative learning assumes a built-in capacity for transfer. Transfer occurs because of the occurrence of specific identical (or highly similar) elements within developmental sequences. Of course, 'elements' here means rules, concepts, or any of the other learned capabilities I have described" (1968). Transfer, in other words, can be counted upon to occur by virtue of the fact that many different terminal capabilities share the same lower-level conditions of learning. After one complete cumulative learning sequence has been traversed, the entire journey will not have to be negotiated again. Other related terminal capabilities can be acquired in shorter order since the learning sequence can begin at a higher level, say at that of concepts, rather than at a lower one, say at that of verbal chains.

The conception of transfer in the cumulative model has two advantages. To be sure, it provides a mechanism for rationalizing the enormous number of capabilities of the adult

human being, but it also leads to the expectation that transfer will not be automatic from the acquisition of some one specific principle to the acquisition of another related one. Consider an example that emerges in Gagné's discussion of work on the acquisition of principles of conservation in children. He notes (Gagné, 1968) that the completion of a learning sequence culminating in the successful performances "judging equalities and inequalities of volumes of liquids in rectangular containers" would not guarantee that the related principle for matching volumes in cylindrical containers had also been learned. In fact, he says, "Probably not, because he (the child) hasn't yet learned enough about cylinders, volumes of cylinders, and areas of circles" (Gagné, 1968). Thus substantial portions of the hierarchies are the same for the two principles, but the identity is not complete. And, wherever two hierarchies diverge, new capabilities have to be learned before transfer can be complete from one to the other. Accordingly, from the viewpoint of cumulative learning theory, the failure of a number of investigations in their attempts to facilitate the acquisition of conservation in children is attributable to incomplete prerequisite learning rather than to insufficient structural growth in the child.

The transfer mechanism in the cumulative learning model, by itself, is probably not sufficient to account for all of the capabilities the adult can display. In fact, to give such an account, it is likely that the cumulative learning model must be extended beyond learning to thinking. Consider, for example, the case of an individual who has learned a set of principles which are all related to similar human performances. Suppose that the capabilities represented by these principles and the subordinate capabilities acquired along the way contain in themselves all of the components necessary for the possession of an additional principle that has in no sense been directly taught. Remember that this instance would lend itself to a transfer analysis in terms of the model only if it were the case that the additional principle represented the apex of an intact hierarchy of learning sequence. Further, then, suppose that this is not the case, that in order for the additional principle to be possessed by the individual, a self-initiated reorganization of existing capa-

bilities would be necessary, some being taken from one specific hierarchy, some from another. By extending the cumulative learning theory to give an account of this kind of process, the model could presumably cover thinking as well as learning. Gagné admits of this possibility when he remarks

[I]t is recognized that such generalizations can readily occur when the individual himself initiates the intellectual activity, the new learning does not have to be guided by external instruction. The process of cumulative learning can involve and be contributed to by the operations of inductive and deductive thinking. The cumulative learning model obviously does not provide a theory of thinking, but it suggests the elements with which such a theory might deal (Gagné, 1968).

In terms of the educational implications of the cumulative model, its greatest service in connection with the problem of thinking could probably be done by providing an explicit specification of the conditions necessary for self-initiated intellectual activity. As we have noted, the existence of such processes must be assumed. But for education as well as for psychological theory itself it is important to know the external and internal conditions that determine thinking processes.

The absence of an elaborated theory of thinking is perhaps the most serious inadequacy of the cumulative model. Without such a component the model cannot provide a comprehensive account of cognitive development. But this is not to say that the model could not be augmented to do so. Indeed, it is one of the model's positive attributes that the sources of its inadequacy are so clearly apparent.

Any complete version of the cumulative model, in addition to containing a theory of thinking, would also need to deal with the necessity for assumptions regarding human capacities that make both learning and thinking possible. Although they are not specified at present, the model seems to assume inherent human propensities for the development of learning abilities and for the development of processing or organizational abilities that are commonly referred to as thinking. Some such assumptions are required by the model because it insists upon specifying explicitly

the conditions under which particular human intellectual activities can take place. Thus one would expect that in cases where neither external nor internal conditions of learning are sufficient to account for observable capabilities, recourse would have to be taken to inherent human capacities.

In general, cumulative learning theory is a strong theory in the sense that it insists upon detailed accounts of the conditions necessary and sufficient to produce the acquisition of any given capability. These accounts, apart from being detailed, must qualify as testable hypotheses as well. Derivations from the theory are eminently falsifiable. In another regard, however, the position is a weak one. For it shares with all other models having a learning emphasis an ultimate indeterminacy if its predictions are not confirmed. As an illustration consider whether or not it is possible to advance intellectual development in children through specific training so that they can successfully evince conservation behavior before untrained age-mates can do so. Suppose that an analysis of the required terminal capability is made and the conditions necessary and sufficient for its acquisition are specified in accord with the cumulative model. Suppose then that these conditions are fulfilled but it is found that the trained children do not, in fact, perform at a more mature level on conservation tasks than relevant control children. Two very different conclusions may be drawn from this result. The first is that a growth model provides a more adequate account of the conditions of cognitive development than a cumulative learning model. But there is an alternative conclusion: the analysis of the subordinate capabilities necessary for the acquisition of the terminal one was itself not sufficient. This second conclusion has the consequence simply of causing the analysis of subordinate capabilities to be modified and then incorporated in a new training sequence. Theoretically the cycle of analysis-training-evaluation can be repeated indefinitely. That is, there is no criterion built into the theory by which a decision can be made that the cumulative model itself is inadequate.

With this much of the basic theory of cumulative learning in hand, we shall turn to an examination of its potential contribution to the construction of a theory of educational

development. In large measure, this task has already been accomplished in its general form as well as in specific applications (Gagné, 1963, 1965a, 1965b, 1965c, 1965d, 1966a, 1967). Obviously, given its hierarchical character and its analytical emphasis, the cumulative learning model would set the starting point of a derived theory of educational development as the statement, in behavioral terms, of the objectives to be attained. Gagné has distinguished six different educational activities to which the cumulative learning model can make contributions:

- 1 Deriving objectives for portions of the educational process directed toward the goals of education
- 2 Describing the various curricula designed to meet the objectives
- 3 Designing the process of instruction
- 4 Designing a system for guiding individual development
- 5 Developing a means to assess student progress in learning
- 6 Establishing a method for evaluation of the means chosen to achieve objectives (Gagné, 1966a, p. 5)

Deriving Objectives for Education. The contribution of the cumulative learning model of cognitive development to the task of setting educational objectives is made largely in terms of the requirements it imposes upon the form in which such objectives are stated. For the cumulative learning model to be of maximal value for education, the objectives must be *comprehensive, systematic, and behavioral*. Comprehensively stated objectives are to be understood in contrast with fragmented statements. This means the objectives of education should be stated for the entire span of time for which formal education is to be imposed on the student. Thus they will be comprehensive with respect to both the full range of contents in which capabilities are to be acquired and the full range of levels of capability to be attained within each content. The objectives should be stated systematically in the sense that they include explicit reference to the hierarchical relationships obtaining between subordinate and superordinate objectives. Thus considerable effort is demanded both in detailing the components of ultimate objectives and in specifying the

priority ordering of the various components. Finally, objectives are to be stated in behavioral terms. The primary justification for such a demand is that if objectives are not stated in behavioral terms it is a matter of guesswork to determine just what it is that the child is to learn. Unless an unambiguous answer can be given to the question "What is to be learned?" there is little hope that the cumulative learning model will make contributions of any substance to education. In addition to this demand for behavioral statements of objectives and the obvious improvement in communication such a practice would entail, other advantages accrue, as Gagné rightly notes:

Unambiguous statements of learning outcomes are necessary to guide the behavior of the teacher. They can be of considerable importance in providing students with immediate goals, and thus in contributing to their motivation. And they are needed as a basis for assessment of the student's progress by means of tests or other measures (Gagné, 1966a, p. 10).

Although the contribution of the cumulative model to the derivation of objectives for education is not a substantive one, it is nevertheless of considerable worth. The implementation of these three requirements—comprehensiveness, systematization, and behavioral definitions—in the formulation of educational objectives would by itself advance educational practice.

Curricular Routes to Educational Objectives. As viewed from the cumulative learning model, curriculum design is a matter of translating behaviorally defined objectives into a designation of capabilities to be acquired. In other words, a curriculum is a statement of terminal capabilities along with the sequence of prerequisite capabilities leading to them. Once the components of a curricular hierarchy are specified, the main task remaining is the determination of the optimal sequence in which the subordinate capabilities should be acquired. The theory of cumulative learning by itself cannot yield unequivocal predictions about such matters. The strategy required is to construct sequences, treat them as hypotheses, and subject these hypotheses to empirical test. The construction of these hy-

potheses is the joint task of subject-matter scholars (mathematicians, historians, philosophers, as the case may demand), curriculum experts, teachers, and psychologists, none of whom can guarantee the superiority of one sequence over another a priori. Examples of the application of this approach have been reviewed by Gagné (1966a).

Stipulating the Conditions of Instruction. By leaning heavily on a learning orientation, the cumulative model draws principally upon research in human learning in specifying its implications for the design of instruction. The kind of information relevant to this task comes from studies that yield reliable conclusions about the conditions external to the learner that yield the most efficient learning, the maximum retention, the widest possible transfer, and the greatest propensity for self-activating intellectual activity. The amount of information available about the first three of these matters is already large and is still growing at a rapid rate. Less is known about the conditions necessary or conducive to self-activating processes.

In his discussion of instructional functions, Gagné (1967) distinguishes seven separate ones. Presumably all of these functions are presently performed by the teacher, but then complexity suggests that a single teacher cannot possibly perform them all adequately in classroom situations. Consequently, Gagné recommends (1967, pp. 309-310) that instruction should be predesigned with regard to the performance of each function so as to reduce to manageable proportions the teacher's task and to insure that the functions are effectively accomplished.

1. Selecting and Presenting Stimuli. Broadly construed, this function is one of the most important in instruction. For the selection and presentation of stimuli must be done with full attention to three considerations: the presenting capabilities of the learner, the fit between the stimuli chosen and the variety of learning to be accomplished, and the extent to which the stimuli are representative of the criterion tasks the learner will be expected to deal with. The task of selecting and presenting stimuli is guided by the cumulative learning model in the following way. A task analysis of the objective of an instructional sequence yields a specification of the subcapabilities and then ordering that are neces-

sary for the attainment of the objective. Each subcapability represents some one of the several varieties of learning that the theory distinguishes. For each variety, external conditions necessary for acquisition would be identified and these conditions would include the relevant properties and manner of presenting stimuli.

Suppose, for example, the objective was to facilitate the performance of pronouncing each of a small set of French words in such a way that native speakers could reliably identify the words uttered. One of the subcapabilities yielded by an analysis of this objective is that of imitating the pronunciation of each of the words immediately after hearing it. If the learner has this capability, then it is appropriate to inaugurate conditions that will assist him in learning to make each of the responses in the absence of the model utterances, that is, given only the presentation of the words in print. Such a task is a multiple discrimination in the terminology of cumulative learning theory and therefore would require the repeated presentation of each of the printed words as stimuli and the evocation of the appropriate responses, probably through a prompting method. Following mastery of the task in this form, prompting would be eliminated and practice would be continued using informative feedback after each response. Thus the stimuli presented in the terminal phase would be identical with those to be used in evoking the terminal performance itself.

2 Controlling Attention Gagné's (1967, p. 305) discussion of this function is limited to an indication of some means for directing the learner's attention to important aspects of the materials presented to him—means such as the use of verbal commands and pointers. The paucity of content on this important topic may reflect a weakness in the theory. Compare this treatment with that reviewed in connection with instrumental conceptualism, where at least a minimally adequate attempt was made to deal with the topic in terms of activating, maintaining, and directing attention. It is interesting to note the contrast between the emphasis in instrumental conceptualism on attentional factors inherent in the stimulus materials themselves and the corresponding emphasis in the cumulative model on extraneous factors.

3 Informing the Learner of Objectives

Gagné views the importance of this function in much the same way that Bruner views the importance of setting forth clearly for the learner the "goals" of his activity. Informing the student clearly about the terminal performance expected of him permits the introduction of informative and effective reinforcements along the way to the attainment of the relevant capability.

4 Stimulating Recall of Subordinate Capabilities This function of instruction comes directly from the cumulative learning model. In order for a superordinate capability to be acquired, subordinate capabilities must not only have been previously learned but must also be recalled at the time the new capability is being learned. Thus it is critical for instruction that methods of cueing be employed that will insure the recall of relevant previous learnings. Although it is not explicitly stipulated, the theory presumably also implies that the recall of these capabilities should be ascertained before instruction proceeds further.

5 Determining a Sequence for Evoking Performance The next step in instruction is to stimulate the learner to engage in relevant activity. An initial move toward this goal is made by deciding upon the sequence of performance that is most conducive to efficient acquisition and durable retention. For example, the decision is whether to present materials in parts or in wholes, whether to institute massed or distributed practice, etc. The term sequence in this connection does not refer to the problem of ordering the presentation of materials relevant to the acquisition of the series of subcapabilities in a given hierarchy—that sort of decision has presumably already been made in connection with the construction of curricular routes to objectives. Similarly, concern with the structure of knowledge to be imparted is nowhere evident in this connection as it was in Bruner's account of instructional functions. But once again it must be pointed out that a concern with structure is subsumed elsewhere in the cumulative model, namely, in the tasks of designing hierarchies of objectives and of curricular routes to each of them.

6 Prompting and Guiding the Learning A second move in the effort to evoke desired performance in the learner consists of the introduction of cues or prompts into the learn-

ing situation. One of the key instructor functions is to provide (usually verbal) stimulation in addition to the central stimuli that are intended by themselves to evoke the desired terminal response. This may consist of providing codes for the use of the learner or information as to what direction to take next in a problem-solving effort. It will be recalled that in Bruner's view this function was incorporated in a concern with the timing and nature of informative feedback as it relates to guiding the learner.

7 Promoting Generalization The last function of instruction is to provide conditions that increase the probability that what is learned will be appropriately transferred to contexts other than those of original learning. Often the conditions of initial learning have a bearing on the extent of transfer and Gagné draws upon the research literature to specify some of these.

Guiding Individual Development The fourth educational activity to which the cumulative model can make contributions is guidance. Guidance here is conceived to have three kinds of relationship to learning. The first is that by providing the developing individual with clear statements of the relationship between learning activities and his long-term goals, positive motivation for continued learning can be maintained. The second relationship between guidance and learning concerns the task of providing the individual predictive information as to the likelihood that his goals can be achieved. But more than this, given an achievable goal, an appreciation of the cumulative nature of learning on the part of the guidance counselor can issue in the establishment of specific sequences of subordinate objectives leading to the attainment of the student's terminal goal. Third, the planful relating of subordinate objectives to terminal ones can itself be a fruitful learning experience, assisting the individual in acquiring the capability for such planning so that he can eventually engage in it without external guidance.

Assessing Student Progress As Gagné has noted, "the effective management of cumulative learning virtually demands that assessment be undertaken at every step of the way" (Gagné, 1966a, p. 19). Since the cumulative model presumes learning to be hierarchical in its organization, the mastery of

lower-level skills is a necessary prerequisite for the acquisition of higher-level capabilities. Instruction, then, cannot succeed unless techniques are used for reliably determining whether or not a student has learned adequately from a particular segment of instruction. If he has not, other conditions of learning must be instituted to insure that he will. Only when the individual has attained a particular objective should he be permitted to commence work toward the next.

The instruments needed for this form of assessment are not readily available. Most tests currently used in schools, even those that are referred to as "achievement" tests, are constructed to permit comparisons between a given individual and his peers rather than between the extent of the individual's mastery of a capability and the level of mastery required for further progress. Gagné (1966a, pp. 20-21) specifies four desirable properties of tests for assessing individual progress. The first is that they be criterion-referenced rather than norm-referenced. Tests should be constructed to reveal the degree of the individual's deviation from the performance required rather than from other individuals in his group. Second, items in such tests should be designed and selected in terms of their capacity for unequivocally measuring the attainment of an objective, not in terms of their level of difficulty. Third, the relation of an item to its attendant objective should be clear not only to the persons who construct the item but to the testee, teachers, and parents. Finally, the meaning of a total test score should be clear to all such persons. Tests designed in accord with these strictures would be truly revolutionary in the field of education and an application of the cumulative model to education is virtually impossible without them.

Apart from assessment techniques and the statement of educational objectives in behavioral terms, the cumulative learning model has a third implication which, if implemented, would be revolutionary in educational practice, it concerns the role of individual differences in educational development. With regard to individual differences, the position of the cumulative model accurately reflects the facts of the school situation, namely, that individual differences are pervasive. The position, predictably, is that instruction must be

"individualized" If successful learning is predicated upon the mastery by any given learner of all subordinate capabilities necessary for the acquisition of a terminal capability, and if children vary in their possession of these prerequisites, then it follows that instructional events must be scheduled to accommodate the status of the individual.

Admittedly, the schools have already attempted to make provision for individual differences through various within-grade grouping practices frequently called "tracking." But tracking is usually decided in terms of performance on norm- rather than criterion-referenced tests. Children are grouped in accord with estimates of their typical rate of learning or of their "intelligence" rather directly in terms of the relevant capabilities they have acquired. Furthermore, the instructional practice that results from tracking is that of presenting to students assigned to "high" tracks more extensive and intensive curricular materials than those in the other tracks receive. Students assigned to the lowest tracks, especially, receive a much reduced curriculum. The learning sequences planned for children in a tracking system, in other words, are not designed to eventually afford all children the same capabilities but instead provide low-track individuals with a simplified version of the high-track curriculum at each grade level.

An alternative means of dealing with the immense variety of learned capabilities and inherent capacities presented by individuals in the schools is the ungraded school. This practice more nearly conforms to the implications of the cumulative model than does the practice of tracking. For in an ungraded school, children are grouped in accord with the level of relevant learning they have achieved rather than with respect to the rate at which they achieved it or at which they promise to achieve a higher level. Only a radically ungraded school, however, would permit the implementation of the full implications of the cumulative model. Only in such a system could all children with a common set of educational objectives be provided with a complete set of opportunities for achieving them. To be sure, objectives would be achieved at different rates, but they would be achieved. This solution is not altogether as satisfying as it initially seems. Consider a

small elementary-level class constituted of children varying in age between 6 and 10 years and in IQ between 80 and 130. Assume that despite the marked variance in chronological age and IQ, all of the children have the same status with respect to measurable capabilities subordinate to the objective of their presence in the class, say, learning to read aloud accurately some specific materials at some specified rate. Clearly, given these characteristics, all children could be provided with the same next set of external learning conditions and learning objectives. It is equally clear, however, that the rate at which those next objectives would be achieved by the members of the class would vary widely. Thus after a short period of time, regrouping would be necessary—in fact, if it were necessary to adhere to some form of homogeneous class composition, regrouping would need to be carried out with great frequency.

Strict homogeneous grouping in this manner would probably prove quite bothersome and virtually unmanageable. The need for it assumes the necessity of teaching children in groups that is, the necessity of group-centered instruction. The cumulative model suggests, to the contrary, that the necessity is for individual-centered instruction where the situation of a single teacher working simultaneously with an entire roomful of children would be atypical rather than commonplace. The operational conditions for individualized instruction are distinguished by Gagné as follows:

- 1 Beginning at an early age, the student needs to learn the general principle that learning takes place as a result of his own intellectual activity.

- 2 The materials constituting the stimuli for learning need to be designed for maximum accessibility and ease of use by the student.

- 3 Each stage of learning needs to begin with a communication that makes the objectives of learning clear to the learner.

- 4 The student needs to be provided with a means of appraisal of his own performance which bears a direct and obvious relation to the objectives of the learning.

- 5 Activities designed to insure transfer of learning need to be provided for, in the form of discussions with the teacher or other stu-

dents, and other opportunities for application of the student's acquired knowledge (Gagné, 1966a, pp 33-34)

It may be inferred from this list that the teacher's function as an interactive figure in the classroom setting is largely confined to the fifth item. His principal functions in such a system have more to do with guiding individual development across instructional segments and arranging for the implementation of the other four items on the list than with being a direct source of knowledge or the primary stimulus to learning in the individual.

To evaluate the educational implications of the cumulative model in more concrete terms, the reader is referred to examples of its implementation with curricular materials. As should be clear by now, the approach required is so detailed that present space is not adequate for describing concrete applications. Some examples of such applications may be found in Gagné and Paradise (1961), Gagné, Mayor, Gaistens, and Paradise (1962), Gagné and Bassler (1963).

As a means of summarizing our examination of cumulative learning theory and its potential for contributing to education, let us try to characterize some of the main features of the model as they relate to education and educational practice. First, the model grows out of the tradition of learning theory and research. It emphasizes the importance of learning, retention, and transfer. But, second, it allows for the learning of units much more complex than elementary connections—units such as concepts and rules or principles. Nevertheless, it is third, adamantly behavioristic in its demands for definitions of objectives in terms of observable performance. Fourth, when the model is turned toward education, its implication is that one must begin with the requirements for successful learning in individuals rather than with the present structure and organization of educational practice, which is largely in terms of classrooms. This feature of the approach may be of inestimable importance, for it means that radical change in educational forms may have to be made. It insists, for example, that the individual student is the prime unit of instruction, not the classroom or the grade level. Thus, fifth, individual differences are to be expected and planned for, not remediated. Sixth, it implies

the necessity for a hierarchically organized, comprehensive, and continuous curriculum design that extends across the entire educational lifetime of the student. And, seventh, continual assessment of student progress forms an integral part of the materials and procedures of learning. The instruments of assessment implied by the cumulative approach are not typical of those used in present practice. That is to say, they are concerned with the student's attainment of behaviorally defined, specific capabilities, not with his performance relative to a norm group. Finally, as we have seen, the cumulative model is weakest when the form of intellectual activity to be installed is at its most complex, that is, when it is a matter of self-initiated reorganization or reformulation of what is already known in the interest of reducing what is unknown. Eighth, as was the case with instrumental conceptualism, the capabilities of the student when presenting himself for instruction are crucial in determining the events to which he will be exposed in beginning his journey through the school. But, and again this is surprisingly consonant with Bruner's position, readiness in the traditional sense is dismissed; readiness is important only insofar as it indicates what it is that the individual has yet to learn, not insofar as it implies that growth must be awaited before the onset of instruction.

OBJECTIVES OF EDUCATIONAL DEVELOPMENT

An attempt to set forth the objectives of educational development reveals the enormity of the work remaining to be done in relating cognitive development and education. The magnitude of the task is produced by at least two factors. It is desirable that the human individual acquire a large number of complex capabilities, and investigations of the conditions that determine the development of these capabilities have barely begun.

It would be desirable to list general objectives of educational development, including broadly described skills and intellectual tools along with a variety of kinds of knowledge from particular subject-matter fields. Presently it is not possible to attain this goal. Instead, we shall have to be content with a very short list of objectives, stated at too general a level and with far too little direct connec-

tion with the psychology of cognitive development. Thus it is important to emphasize that the gaps in need of spanning are cavernous.

Let us begin by agreeing, at least provisionally, that education has two objectives to facilitate the development of (1) the most intelligent and (2) the most productive forms of thinking possible in individuals. Alternatively, the terminal objectives of education may be said to be those of maximizing intelligence and creativity. Obviously, neither of these phrasings is satisfactory, for we must go on to say what we mean by intelligence and what we mean by creativity. Considerable effort has gone into attempts to specify the referents of the two objectives and to explicate the relationship between them. Notable contributions have been made by Guilford (1950, 1959), Crutchfield and Covington (1965), Mackinnon (1960), Torrance (1962), and Getzels and Jackson (1962).

The most straightforward and, at the same time, the most unsatisfying referent of the term intelligence is the score obtained on an intelligence test such as the Wechsler or the Binet. With respect to education, a high IQ is unsatisfying as a criterion because the performances required for such an outcome seem not to be representative of the capabilities sought through the process of schooling. The

idea of using a criterion such as test performance as an objective of education, however, has a very attractive feature, it is a behaviorally defined objective that is widely understandable. The critical thing is to select the criterion properly and this means thinking in terms of multiple tests rather than a single one.

Guilford (1959, 1967) has constructed a general mode of intelligence that accords with this stipulation. The method followed in building this structure-of-intellect model consists of two major strategies. The first is to apply factor analytic techniques to intercorrelations among scores on a wide variety of measures of intellectual functioning. Such analyses have yielded factors that have been grouped into three principal dimensions. The second strategy is to cull from the psychological literature possible additional factors which, when combined with the original set, form a logically exhaustive list. The resulting model predicts at least 120 separate abilities, each of which is determined by one or more factors of intellect. This rather long list of abilities is yielded by the intersection of the various components arrayed along three dimensions that describe the structure of intellect. The dimensions and their components are as follows.

<i>Operations</i>	<i>Contents</i>	<i>Products</i>
Memory	Behavioral	Units
Cognition	Figural	Classes
Divergent Thinking	Symbolic	Relations
Convergent Thinking	Semantic	Systems
Evaluation		Transformations
		Implications

Theoretically, any one of the operations can be carried out upon any one of the kinds of content and can result in any one of the kinds of products listed, as when the evaluation of symbolic content results in transformations. For example, consider the task of choosing the one of two series of scrambled letters that contains a meaningful English word and then unscrambling the one chosen. In doing so, a subject evaluates symbolic units in making his choice between the two series and transforms the one chosen in order to produce an English word.

Whether or not these 120 capabilities turn out to be accepted goals of education is not of prime importance for our purpose here.

Agencies other than or at least in addition to psychological ones will have to be involved in determining whether or not these abilities constitute acceptable educational objectives.

The striking features of the model are that it specifies a large enough number of varieties of intelligence to be comprehensive and it identifies each one in terms of observable performances on concrete tasks.

When one examines these tasks, it is clear that they do not sample adequately in any sense from particular subject-matter areas that usually form the mainstream of school curricula. If capabilities in particular subject-matter areas form the objectives of education, then the structure-of-intellect model is pat-

ently insufficient. This conclusion should not be construed as foregone, however, since it is possible to conceive that the primary objective of education may cut across subject-matter specialties and thus fail to represent adequately any one of them. For example, a principal educational objective might be to foster efficient learning of symbolic relations. Such a capability is not specific to any particular subject-matter area but is of clear relevance to a variety of school subjects and might be acquired in the course of learning, say, mathematics, logic, physics, and political science.

In Guilford's view, the structure-of-intellect model includes what we have referred to as creativity or productive thinking as well as what we have called intelligence. Other researchers have pointed out that in its usual sense, that is, performance on an IQ test, intelligence does *not* encompass creative or productive thinking. Getzels and Jackson (1962) evaluated the abilities of secondary-school students on both an intelligence test and a creativity test. The creativity test included items drawn from those mentioned by Guilford (1959) as measures of divergent thinking. One of the results of the investigation was that of the highest 20% of students on creativity tests, 70% did *not* score in the highest 20% on the intelligence test. The conclusion is that since these two forms of intellectual capability are not inextricably tied, neither one, by itself, is a sufficient criterion of intellectual development. Torrance (1960) confirmed the Getzels and Jackson (1958) results for younger children, grades one through six.

A cautionary note must be sounded before proceeding further. Thorndike (1963) has pointed out that the use of the term "creativity" to refer to a single capability as measured by the tests of divergent thinking used in these studies may be unwarranted. His argument turns on the fact that the inter-task correlations among "creativity" tests are relatively low as compared with similar inter-correlations among subtests on standard tests of "intelligence." The point is that for the intelligence tests there is some reason to assume a single underlying ability, whereas several discrete abilities appear to determine performance on creativity tests.

On the basis of these findings, Getzels and

Jackson (1962) and Torrance (1960) emphasize that schoolmen should recognize the intellectual validity of creative capabilities and should incorporate this recognition in their efforts to guide the educational development of highly creative students of moderate IQ. A more radical view can be taken, however, as illustrated by the position of Crutchfield and Covington (Covington, 1967a). In brief, their thesis is that productive or creative approaches to a wide variety of intellectual tasks should form the central core of the school curriculum. It follows that particular content areas—mathematics, English, social studies—should simply provide concrete materials in terms of which to permit students to practice and perfect their use of the skills of productive thinking. According to this view, the objectives of education are to promote effective use of a variety of thinking skills across widely differing subject-matter areas. Notice, however, that these objectives are not defined behaviorally, at least not if they are conceived as the goals to be attained by the end of secondary school.

Nevertheless the work of Crutchfield and Covington (1965) has been quite concrete and has produced definite behavioral criteria of productive thinking capabilities. The criterion test battery used by these investigators has included three kinds of tasks. In the first the child is required to solve problems that vary with respect to the amount of constraint inherent in the initial statement of the problem. For example, two of the problems that have been used are (1) to discover methods by which gigantic ancient statuary might be saved when the valley in which it is located is flooded by the building of a dam, and (2) to explain an apparent change in location of a nearby house during a single night. The second kind of task consists of several tests of divergent thinking that require the child to produce, for example, several consequences of some hypothetical event such as a world-wide increase of 5 inches in sea level. Third, the criterion battery has included inventories designed to index attitudes toward self, intellectual activity, and intellectual tasks. Unfortunately, the research of Crutchfield and Covington has so far been limited to individuals of approximately fifth-grade age. Hence considerable systematic work remains to be done across both later age spans, and prob-

ably the preffth-grade yeais as well, before it will be possible to give explicit behavioral definitions of terminal educational objectives. Moreover, the work to date has not incorporated content that is germane to customary school subjects, so that it is not possible presently to judge the potential of this appioach for replacing the commonly accepted prime purposes of education. Clearly this kind of revolution cannot come about quickly and for the moment it appears the contribution to education of the productive-thinking appioach will be auxiliary. Even so, it seems clearly to be a salutary adjunct to the current emphasis on discipline-bound instruction.

After these few examples of educational objectives produced in the course of work by psychologists on problems of intellectual functioning, we still must consider what contributions developmental psychologists can make to the setting of educational objectives. This consideration is not a simple matter. The setting of educational goals is not the task of the psychologist, but he can contribute to both the formulation of goals and the setting of objectives in at least three ways. First, he can broaden the view of educators by carefully isolating and describing the range of intellectual attainments that are within the reach of human beings. Second, he can make concrete, in behavioral terms, the meaning of these attainments, that is, he can inform the schoolman about overt indicators of the possession of such capabilities. Finally, he can provide evidence about the consequences of various kinds of environmental intervention, that is, instructional or educational intervention, for the attainment of these objectives at various points in the development of the individual. The work of psychologists concerned with intelligence and creativity illustrates the first two kinds of contribution. The present status of the work is such that it qualifies only as illustration because it has not been truly comprehensive nor has it been adequately correlated with the requirements of the schools. The third kind of contribution, providing information graded developmentally about the effects on later intellectual functioning likely to result from specific kinds of earlier training, involves an examination of the entire topic of curricular routes to educational objectives.

CURRICULA, CAPABILITIES AND EDUCATIONAL OBJECTIVES

In educational terms, the means for guiding students to the attainment of educational objectives are the curricula that describe the sequence and content of schooling. What are the curricula that will best lead to intelligent and productive behavior by the end of secondary school? In psychological terms the task may be described as that of isolating the subcapabilities or subskills necessary for intelligent and productive behavior, specifying the conditions that promote the acquisition of these capabilities, and discovering the optimal timing and sequence in which to impose these conditions in view of the presenting status of the individual. The last two psychological components of the curricular task will be taken up in subsequent sections of this chapter. Our present concern will be with the matter of isolating and specifying the subskills necessary for intelligent and productive behavior.

When reviewing the work of psychologists relative to the topic of acquiring capabilities, one is struck by the disproportionate distribution of effort at the lower end of the age range. Comparatively, the amount of theory and evidence available for preschool and primary-school children is massive and that for secondary-school age groups is slender indeed. Some of the possible reasons for this state of affairs are worth mentioning. One is that the terminal capabilities expected of the secondary-school graduate are highly complex, involving as they do the structure and contents of a variety of scholarly disciplines. In contrast, the terminal capabilities expected of a third-grade student are simple indeed, although they still defy a completely satisfying account in terms of psychological theory. Since the nature of psychological research is slow and painstaking, it is no surprise that the amount of progress made in describing and understanding the cognitive capabilities necessary for attaining terminal secondary-school objectives is quite small relative to the overall dimensions of the task. A second reason is that the kind of research most often conducted by psychologists, especially experimental psychologists working on problems connected with topics of cognitive development, is most relevant to the kinds of

educational capabilities demanded of pre-school and primary-school children. Consider the instance of the experimental psychology of verbal learning (see, e.g., Cofer, 1961, Cofer and Musgrave, 1963, Goss and Nodine, 1965). To be sure, the subjects in verbal learning studies are drawn most often from college-age populations. Nevertheless, the tasks set for the subject and, consequently, the referents of generalizations issuing from the experiments, are more applicable to the learning that occurs in kindergarten and the primary grades than they are to the learning a student is expected to manage in college. The memorization of lists of single items, whether according to a serial, paired-associate, or free-recall paradigm may be characteristic of school tasks in the early grades but not at the college level. For these and other reasons, the consideration that will be given here to potential contributions of psychology to curricula will be heavily concentrated in the pre-school and primary-school period. Nevertheless, we shall begin at the other end with a discussion of elementary and secondary curriculum developments to which a psychology of cognitive development can contribute.

Elementary and Secondary Levels

Most of the research activity directed toward constructing curricula for promoting the attainment of terminal educational objectives has been concentrated in mathematics and the sciences. Although it started somewhat later, there is now promise that a similar substantial outpouring of effort will occur in the areas of English and various social studies as well. Our present scope will be limited, including only the topics of mathematics and creativity as they pertain to newly constructed curricula for elementary- and secondary-school children. Other curricular areas could be included as well, but due to the presently minimal contribution of developmental psychologists, they will be omitted. Curricular developments in the areas to be reviewed are, in some cases, relevant for the younger age groups as well. But for now, we follow present educational practice and recognize a major juncture at the interface between primary and later elementary education.

Mathematics The amount of work in mathematics education is presently quite sub-

stantial and well-received in school systems. Numerous projects have developed in which full-scale curricular construction programs have been undertaken. Among those having already received considerable attention from educators are the School Mathematics Study Group (SMSC) (see Begle, 1958, Cahen, 1963, Weaver, 1963), Madison Project (see Davis, 1963, 1966), University of Illinois Arithmetic Project (see Hohn, 1961, Deans, 1963, Page, 1962), Sets and Numbers Project (see Suppes, 1964, 1965, Suppes and Hill, 1963, Suppes and Ginsberg, 1962, Suppes and McKnight, 1961), and the University of Maryland Mathematics Project (see Gagné and staff, 1965). To greater or lesser degrees, these projects have taken the reworking of the entire mathematics curriculum as their task, some pertain to the elementary curricula only and others to junior high school curricula as well. In general the "new math" as represented here marks a shift away from the presentation of commercially relevant arithmetic ideas to an emphasis on central mathematics concepts as conceived by mathematicians.

Relative to these efforts, the questions we shall consider are: What have been the contributions of psychology? And what additional contributions might be made? The answer to the first question is that the contributions of psychologists to the construction of these mathematics curricula have varied from one project to the next. The contributions of Suppes to the Sets and Numbers project and of Gagné to the Maryland Mathematics project have been quite central. Suppes' approach (Suppes, 1964, 1965, Suppes and Hill, 1963, Suppes and Ginsberg, 1962, Suppes and McKnight, 1961) has been notable in several respects. The construction of the materials, the mode of presentation, and methods of practice instituted were informed by a psychological theory, specifically a modified version of stimulus sampling theory, the efficacy of the materials used has been evaluated systematically, and an analytic concern with basic theoretical questions of the nature of concept learning, concept transfer, and generalization has issued in concurrent experimental studies designed to shed light on these issues. For example, some of the early objectives of the Sets and Numbers first-

grade curriculum are the acquisition of the notions of sets, identity of sets, equipollence of sets, and ordered sets. These notions are presented in a workbook, frequently by means of figural illustrations, and students respond by answering multiple-choice questions that assess their understanding of the concepts given.

In initially constructing curricular materials of this kind and in seeking to revise and improve them, questions arise regarding the optimal sequencing in instruction of the series of concepts, the stimuli that should be used to present the concepts, and the sorts of responses to require in order to improve transfer and generalization of the concepts learned. Suppes and his colleagues have conducted empirical studies designed to provide answers to these questions. One of the laudable aspects of the studies is that the materials were very similar to those used in the Sets and Numbers curriculum. Suppes and Ginsberg (1962) have summarized the results of such studies with young children (kindergarten and first-grade): learning is more efficient if errors are corrected immediately, incidental learning of concepts cannot be expected, concept transfer is enhanced when the child is required to recognize the presence or absence of a concept in a display rather than simply matching one display with another, and learning of the concepts of identical, equipollent, and ordered sets is quite specific—the learning of one of these does not appear to facilitate the learning of another. Attention has even been given to some developmental questions in terms of an appraisal of how children of different ages respond to a series of questions demanding logical inference (Hill, 1961).

As reported by Gagné and others (1965), the contribution of psychology to the Maryland Mathematics project has also been quite substantial. Predictably, the contribution in this case has been in terms of specifying behavioral objectives, constructing the materials in accord with a hierarchical analysis of the capabilities necessary for acquisition of the terminal skill, and evaluating the effects of previous attainment of subordinate capabilities on the ease of attaining a superordinate capability. In particular, one objective was that of "specifying sets, intersections of sets, and separations of sets, using points, lines and curves." Analysis of the objective yielded

a number of subcapabilities (e.g., identifying and drawing a plane, identifying and drawing a curve) and experimental learning programs were constructed to promote the acquisition of these skills. Among five programs, the number and variety of examples used for each subskill were varied. The efficacy of the programs was evaluated by posttests designed to measure performance with respect to both terminal and subordinate capabilities. The results indicated that number and variety of examples were not effective variables and provided confirmation for the notion that the acquisition of a capability depends upon the previous acquisition of subordinate capabilities.

The role of psychological theory and methodology apparently has not been as central in many of the other projects, certainly it has not been as visible.

This brings us to our second question: What psychological contributions might be made to the development of mathematics curricula? At the risk of redundancy, it must be said that there is room and need for collaboration at a number of points in such curricular efforts. In addition to those functions already mentioned, specifying objectives, analyzing the necessary steps to curricular objectives, and sound evaluation, a psychology of cognitive development can contribute substantially in other ways. It can focus concern upon questions regarding the acquisition, retention, generalization, and transfer of concept learning in the case of both simple and complex concepts of the sort involved in mathematics (see Morisset and Vinsonhaler, 1965, pp. 102-108).

But there is still another kind of contribution that a psychology of cognitive development can make to the development of mathematics curricula. There is an almost entirely unfilled need for assessing the efficacy of curricular materials developmentally both as a function of the age of the students and as a function of their previous relevant learning. An available but quite limited example of this approach is provided in a study reported by Joyce and Joyce (1964). Their aim was to evaluate the ease of acquisition of some of the concepts involved in SMSG curricula by fifth- and sixth-grade children. A preliminary assessment was made of the ability of the subjects to perform both concrete and formal operations so that

controls for this ability could be built into the study. The pretest results revealed that the sixth-grade children were superior to the fifth-grade children in their capacity for formal reasoning. Nevertheless, children from both grades derived significant benefit from the SMSG materials. More complete assessments of this kind are needed both with respect to the ease of acquisition of a particular mathematical capability and with respect to the effects of acquiring a given capability at one age rather than another on the acquisition of other capabilities. That is to say, an experimental examination should be made of an interaction between age and particular training contents with respect to the amount of savings produced in the later learning of some transfer task (see Cionbach, 1965, Mussen, 1965). Such curricular involvements on the part of psychologists concerned with cognitive development would facilitate efforts to answer psychological questions as well. Too little is presently known about concept development in the realm of complex, well-structured subject matters and it is precisely from investigations of the sort mentioned that advances are likely to come.

These comments apply equally well to current developments in the area of elementary and secondary science curricula. Brief descriptions of some of the more visible programs in this area may be found in the *Review of Educational Research* (Atkin, 1964, Hurd and Rowe, 1964, Leiderman, 1965).

The observational studies of Piaget (see Flavell, 1963, and chapter by Flavell in this book) have had some influence upon those working in the area of science curricula, as well they might have. Again, the need is for systematic planning and execution of psychological research in the various phases of these projects rather than for additional influential theoretical pronouncements. The presentation of concepts and the attempt to institute conditions that facilitate their acquisition is a principal task of efforts in science curricula programs, a task that encompasses some of the central concerns of psychologists interested in cognitive development. And yet, only in exceptional, scattered cases has the form of collaboration necessary to yield fruitful psychological information and enduring educational contributions been instituted.

The type of supporting research that permits one to assess how well one is succeeding in the management of relevant instructional variables requires a constant and close collaboration of teacher, subject-matter specialist, and psychologist. As intimated earlier, a curriculum should be prepared jointly by the subject matter expert, the teacher, and the psychologist, with due regard for the inherent structure of the material, its sequencing, the psychological pacing of reinforcement, and the building and maintaining of predispositions to problem solving. As the curriculum is being built, it must be tested in detail by close observational and experimental methods to assess not simply whether children are "achieving" but rather what they are making of the material and how they are organizing it. It is on the basis of "testing as you go" that revision is made. It is this procedure that puts the evaluation process at a time when and place where its results can be used for correction while the curriculum is being constructed (Bruner, 1966d, p. 70).

Two additional dicta should be mentioned. The first may simply be a matter of giving greater emphasis to the importance of explicitness in research done in support of curriculum development. Ingenuity and flair are not enough to effect enduring and extensive changes in education, however much virtuosity is involved. Only with painstaking efforts at specifying objectives in terms of the behavior expected of students and at specifying methods, materials, and procedures in terms of the behaviors expected of *teachers*, can full impact be made. The second addition concerns the form of the research to be carried out in connection with curriculum-building. Such research must be designed with the intent of contributing directly to psychological understanding of the basic processes in cognitive development. This means planning studies that conform to the demands of experimental design in order that valid inferences may be drawn.

It also means using designs that will permit the testing of developmental hypotheses—providing, in other words, for an adequate assessment of possible interactions between age, past experience, sequencing, and treatment components. The point is not that psychological training is crucial for the initial creation of

curricular materials—it is not. Rather, the point is that a psychological contribution is necessary if we are ever to know anything about the effects of new curricula and if we are ever to learn anything lasting from curricular efforts about the development of the human mind.

Creativity Research and development related to curricula and creativity are burgeoning activities. At least two different approaches to these problems may be distinguished. One holds that the acquisition of any subject-matter ought to be infused with creativity (Suchman, 1960). The other holds that the cognitive processes involved in creative thinking are themselves worthy objectives of education and therefore ought to be taught (Covington, 1967a). Both approaches arise from the assumption that one of the most important potential outcomes of schooling is the ability to approach both knowledge and the unknown in a self-activated manner with well-developed skills for both the acquisition and the discovery of knowledge. Both approaches have produced curricular materials and programs that follow from their assumptions. And both approaches have achieved a modicum of acceptance for actual school use. Nevertheless, the differences between them are important, since students learn different things from the two forms of training.

The point of those that are committed to the importance of creativity or productivity as a major objective of education is well taken, the specific contents of subject-matter areas are transitory, and education therefore cannot take as its sole objective that of assuring the memorization of existing knowledge which is likely to become obsolete soon after it is acquired.

The argument is persuasive but it is important to note that there are variations on it. One version has it that the crucial thing is to teach children creative habits of inquiry as they acquire the subject-matter that the schools normally provide. A second version starts by noting that creativity or productive thinking cannot occur in the absence of some kind of concrete materials with which the student can be productive or creative. It finishes by arguing that being creative means being creative in one field or another, and creativity in a field can occur only *after* the subject matter of the field has been so over-

learned as to free the individual from the task of comprehension and retention (Eisner, 1963). The third approach takes the view that unless the capabilities for creative thinking are taught as a subject in their own right, they will not be learned well or retained for long since the principal content of learning will inevitably be that of the subject matter at hand (Covington, 1967).

The absence of decisive empirical evidence means that a definitive choice among these variations on the theme of creativity in educational development cannot yet be made. It is also clear that they are not mutually exclusive, except in the sense that limits on educational time and educators' energies may prevent their simultaneous implementation. Few would disagree that for some children, at some ages, with particular backgrounds of experience in connection with some subject matters, learning through discovery (methods through which students are led to arrive at principles by induction after being given examples) is a good thing. Equally few would disagree that despite the danger of early obsolescence there is much benefit to be derived from mastery of a field followed by creative contributions to it (although many would stipulate that excessive focus on mastery precludes originality). Finally, few would disagree that if it is possible to create curricula having the sole objective of installing capabilities for creative thinking, it is worth doing.

Despite all of this potential complementarity among the various conceptions of the place of creativity in education, our focus here will be on only the one associated with the work of Clutchfield and Covington (1965). The conception identified with Suchman (1960), the Inquiry Method (discussed later), when viewed in connection with creativity properly belongs in a more general discussion of the conditions that facilitate educational development. The version associated with Eisner (1965), which holds that mastery of subject matter must precede creativity, represents a distinct position on the issue of fostering creative thinking but hardly seems capable of generating a curriculum directed toward that objective. Thus our focus for the remainder of this section will be upon the third version, that concerned with directly promoting skills

of creative thinking through curriculum development

This approach is well-represented by work done in the Creative Thinking Project under the direction of Crutchfield and Covington (Covington, 1967a, 1968, Covington and Crutchfield, 1965, Crutchfield and Covington, 1965). The objectives of the curricula developed by these investigators are to foster *dispositions* toward engaging in tasks that permit of creative thinking, positive *attitudes* of the student toward himself as a productive thinker and toward intellectual activity, and *cognitive skills* that do, in fact, improve the individual's ability to think productively.

An auto-instructional program was constructed to facilitate the attainment of these objectives.

The program consisted of a series of simplified detective and mystery stories. Such stories were chosen because they interest children, because they effectively combine many of the essentials of the problem-solving process, and because they can deal with a variety of situations which cut across curriculum content areas.

Each lesson posed a single mystery which the child was to solve. The lesson was constructed so that the child, by being given a succession of clues and information, was finally led to discover the solution for himself. At various points in the story sequence, the child was required to restate the problem in his own words, formulate his own questions, and generate ideas to explain the mystery. Feedback to his responses was given on following pages in the form of examples of ideas or questions that he might have thought of in the given situation. These examples were primarily ones which fifth- and sixth-graders would find novel and uncommon, and which would open new lines of investigation or new ways of viewing the problem. It was assumed that the exposure to numerous examples of this type would tend to broaden the child's vision and limits of acceptance as to what constitutes important questions and fruitful ideas.

A story line was maintained throughout the lessons by developing a narrative concerning two school children (named Jim and Lila, brother and sister) as they learn to become detectives by taking lessons from their uncle, a high school science teacher who is a spare-

time detective. The novel and uncommon responses given as feedback to the student were presented as Jim's and Lila's ideas. Thus, the student could work on the problem in concert with Jim and Lila—first the student generating his own questions or ideas, then Jim and Lila responding with theirs. This allowed the student to participate in the solution of problems with a pair of curious and imaginative children, one male and one female, who acted as models to be emulated. The models were not meant to be perfect, they make mistakes, but learn by them. From being poor problem solvers at first, they develop their skills progressively to become much better ones. It was hoped that identification with such realistic models would induce in the student a sense of his own progressive improvement in thinking skills as he worked through the program.

These stories were presented primarily by cartoon illustration in a booklet format. It was assumed that such visual presentation would not only increase the student's interest in the material, but would make it easier for him to follow the dialogue and thought sequences of the story characters.

The training program consisted of 13 lessons with an average of 30 pages per lesson. Each lesson was self-administering and self-paced. The program was of a linear type with primary emphasis on constructed responses (Covington and Crutchfield, 1965, p. 3).

The method formulated for achieving these objectives has at least three aspects that are instructive for our concerns here. First, it issued from a sensitivity to conditions of educational practice. That is, the materials that were constructed for fostering creative thinking were designed to be self-administering. This has two obvious advantages: the program is *relatively* less subject to between-classroom variability than those in which the teacher is the crucial source of information, and the materials are in a form that can be adopted by schools without extensive training and indoctrination for teachers who are to use them.

The second notable aspect of the method adopted by the Creative Thinking Project is that the creation of the instructional materials themselves was not stringently guided by psychological theory and research, although in an

informal manner there is no doubt that it was influenced by them. Whether or not this is a virtue depends at the present time upon the observer's bias more than upon evidence, since it is yet to be determined whether or not materials generated by deductions from theory produce superior results.

The point to be emphasized is simply that the principal contribution of a psychology of cognitive development to a curricular effort may not be through the initial construction of materials. For example, the construction of one program produced by the project, the General Problem Solving Program, proceeded somewhat as follows. It was decided to create materials for use with fifth- or sixth-grade elementary-school children. A few preliminary lessons were constructed and administered to groups of children in these grades. The lessons contained provisions for the children to respond at various points throughout each one and on the basis of these responses the lessons were revised and extended. Additional lessons were added and subjected to the same sort of preliminary testing and evaluation. The process of pilot work continued until a more or less complete series of lessons had been evaluated in a preliminary way. Then full-scale empirical studies were made of the effectiveness of the materials. Note that at no point did scientific information about the cognitive structures of children in the target age range play a crucial role in the design of the materials, nor did methodological strictures coming from research on programmed instruction, although both kinds of information contributed in a background fashion.

The third aspect of these materials that is worth special attention is concerned again with their self-administering character. This feature of the program permits accommodation to individual differences, at least with respect to the characteristic paces at which students are able to traverse instructional lessons. Admittedly this marks only a first step in taking account of individual differences in curriculum making, but it is at least that.

The question remains: What sort of contribution can a psychology of cognitive development make to a curriculum effort such as that of the Creative Thinking Project? The question must be answered in terms of the unfulfilled needs that such a project has in the absence of such a contribution, needs that

can be clarified by examining the results of the introduction of the program in elementary-school classrooms.

In the best designed of the studies using these materials, they were administered to fifth- and sixth-grade children in classroom settings. Within each classroom, children were assigned to two groups at random, in one the General Problem Solving Program was administered, whereas in the other a placebo program, concerned with state history, was administered. Prior to the onset of training, an extensive battery of pretests was given to all children. These pretests were paralleled by posttests administered at the end of training. A variety of tasks was used for this purpose, including a number drawn from those developed by Torrance (1965), a number of problems to be solved, some created especially for this project, others, such as Duncker's X-ray problem, drawn from the literature on problem-solving. In addition, some other unique problem-solving tasks have been developed to permit an assessment of the child's preference for intellectual as against clerical activity (see Covington, 1967). Finally, the battery includes an inventory designed to assess attitudes toward self, school, and intellectual activity.

At the conclusion of the pretest, the training is begun and administered at the rate of one lesson per day for a total of some 16 school days. Each lesson requires approximately 30 minutes of time for completion, so that it is not excessively disturbing to a school schedule. The contents of the program are fully described by Covington (1968). Suffice it to say here that the child is induced to engage in activities such as generating ideas, evaluating ideas, suspending criticism, forgoing premature fixation on solutions, noticing subtle hints and clues to problem solution, and reformulating information. These activities are tied together through the medium of a story-line presentation of the problems, in which continuing characters engage in activities that are replete with puzzling phenomena and problems to be solved.

The results in a number of replications of variants of this same study consistently show that children who receive the General Problem Solving Program perform significantly and substantially better on criterion tasks, gain more from pretests to posttests, show greater

changes toward positive attitudes toward self and school, and show a stronger disposition to formulate problems and engage in their solution than do the control children. In general, greater benefits are derived from the program by fifth- than by sixth-grade children. In sum, the effort to improve capabilities relevant to problem-solving and other related forms of productive thinking has been eminently successful.

We now return to our central concern with what kind of contribution the study of cognitive development can make to an effort such as this one. There are many possible answers to this question. The program described has been successful as judged by performance on criterion tasks but very little is known, so far as can be determined from reports presently available, regarding the reasons for its success. That is to say, the task of isolating the components of the treatment that determine its success has not been accomplished. Until it is, the utility of the approach is limited to the specific materials produced. Similarly, the question of whether or not the training provided by the program facilitates acquisition of other capabilities is entirely indeterminate. The differential effectiveness of the training materials for fifth- and sixth-grade children suggests that a systematic developmental study is needed to reveal the limits of effectiveness of the present form of the materials and to isolate the determinants of these limits. Finally, the kind of information that could be yielded by a psychological analysis of the present program in terms of basic processes in cognitive development promises to permit modifications and additions that would strengthen its effectiveness. These, then, are some of the contributions to this particular form of educational practice that might be made by those interested in research and theory in cognitive development.

In order for a child to profit from the General Problem Solving Program or from any of the other curricular materials that involve the child in obtaining information from printed materials and giving evidence of his possession of the relevant terminal capabilities, he must already possess some lower-order capabilities. One of these, reading, long formed the heart of the primary-school curriculum. Thus we next consider the contributions that

the study of cognitive development can make to the acquisition of this capability.

Primary Level

Present educational practices have changed sufficiently that children are asked to learn more in the primary grades than reading, writing, and arithmetic. Indeed, most of the curricular topics we have considered are taught in primary school as well as at elementary and secondary levels. Nevertheless, the acquisition of the capabilities involved in reading persists in being one of the very major concerns of schoolmen responsible for primary-school education. Not only is reading central in the primary-school curriculum—it is also problematical. For much too large a percentage of children do not learn to read well, or in some cases at all, by the end of the third grade. Furthermore, reading is properly taken up at this point in our discussion because it is prerequisite for much other later learning.

Reading is well worth our attention for another reason. It provides a clear illustration of the point that the relevance of research for educational practice does not guarantee that it will effect changes in practice. The recent book by Chall (1967) provides striking documentation of the plethora of research that has been done on reading and the paucity of effect that it has had. True enough, the results of some studies were not unequivocal. But, even where the results were clear, as in their indication that "code emphasis" methods of promoting beginning reading are superior to "meaning emphasis" methods, their impact on practice has been negligible.

Thus it is appropriate to state again the distinction that has recurred throughout this discussion of the relationship between cognitive development and education. The first step in accomplishing a liaison between the two fields is the growth of research that in one way or another pertains to schooling problems. This is the step that psychologists of cognitive development can themselves accomplish in substantially effective ways. The next step, however, does not follow inevitably from the momentum generated by the first. The step of effecting change in educational practice requires methods and procedures beyond those required for research and theory construction in cognitive develop-

ment It requires the creation of curricular materials suitable for use in schools, well-managed introduction of those materials into the schools and, at least at the beginning, relatively constant monitoring of their use to insure that it continues beyond, let us say, the first week After this has been accomplished—in fact, while it is being accomplished—the psychologist's methods can make additional contributions to the goal of evaluating the materials constructed, indicating modifications or diversifications of them, and determining the conditions under which their effectiveness is maximal But these functions are to be distinguished from those necessary for the actual use of the products of research in daily educational practice The necessary functions must be carried out as well or it seems probable that the best of research in cognitive development will come to very little in terms of the improvement of education

As we saw to be the case for curriculum developments in mathematics and creativity, research activity in connection with reading has burgeoned Of all the curricular developments reviewed thus far, however, the contributions of the study of cognitive development are far more exciting in connection with reading than in any other The talents and concepts of many psychologists interested in cognitive development have turned to the problems of reading and the results of the investigations and speculation that have ensued are fascinating Those interested in perceptual development, learning, language acquisition, psycholinguistics, sociolinguistics, and even psychophysiology have made provocative contributions to these developments A perusal of the tables of contents of the various *Project Literacy Reports* reveals the breadth, variety, and intensity of interest that has been generated in research related to the topic Among the reviews that have recently appeared, those by Williams (1965), and by Keifoot (1967) provide another index of these developments

In work related to the problem of reading instruction, the overriding strategy of developmental psychologists has been to analyze the process into its components and to subject these components to experimental and theoretical analysis These analyses, as we shall see, have not yielded uniform results, nor have empirical investigations yielded uniform

interpretations and speculations, but they do share a concern for specifying the processes that underlie the acquisition of reading skills In other words, the method of attack has been to ask about the subskills that are prerequisite to the acquisition of the capability of reading It is important to recognize that the present status of this relatively new work on the components of reading skills has not advanced sufficiently far to have promoted the development of validated instructional materials for the teaching of reading Thus the remainder of our discussion of this topic anticipates our next concern—the general categories of basic cognitive skills that must be presupposed if any of the kinds of learning that are commonly identified as school learning can go forward

Much of the current basic research on reading has been conducted by a number of investigators loosely organized into a consortium called Project Literacy In reviewing studies done within the Project, let us begin with a psychological analysis of reading capabilities, which is notable for its clarity and for the quality of the research it has generated (Gibson, 1965a, 1965b) Gibson divides the acquisition of reading skills into four stages that form a developmental sequence

- (1) Learning speech, in all its aspects such as hearing, comprehending and producing it,
- (2) learning to differentiate graphic symbols,
- (3) learning to decode graphic symbols to speech, and
- (4) progressive utilization of the higher-order constraints and regularities in the system, the system being considered as an intermodal, graphic-phonetic set of correlations (Gibson, 1965b, p 1)

We shall not consider the first stage until we have discussed the more general problem of language development Gibson's approach to the second stage is of considerable interest Drawing upon the work of Jakobson and Halle (1956) on distinguishing among phonemes in terms of their unique patterns of distinctive features, Gibson (1965a) has developed a scheme for analyzing letters in a similar fashion The original list of features includes such things as the directionality of straight lines and open and closed curves, if any, that form the letters Using this list of features as an index of interletter similarity,

a modicum of success was achieved in an attempt to predict the relative confusability of letters. In another study (Yonas and Gibson, 1967) it was found that children as young as those in a second-grade sample could make use of the feature of diagonality in a task requiring discrimination among two sets of letters, the sets being defined by the experimenter.

These two studies, by themselves, do not establish the hypothesis that learning to discriminate letters is a perceptual learning task in which the child makes use of the distinctive features first developed. Accordingly, the implications for education are not direct. Nevertheless, work to date does suggest that it would be worthwhile to develop an instructional sequence for letter discrimination in which heavy reliance would be placed upon techniques for highlighting the distinctive feature properties of letters.

Work on the third stage of reading acquisition began with studies of the effects of learning single-letter to single-sound correspondences. Bishop (1964) showed that transfer of such learning to new words was successful when component correspondences had been learned as individual units but not when learned by a whole-word method. The implication here, of course, is that regular correspondences ought to be taught and that some successful means of instruction should be found. But before this effort is expended, Gibson and her colleagues suggest that a critical prior question must be answered: What is the primary psychological unit of spelling-to-sound correspondence? Their answer, drawing on the work of Hockett (1965) and Venezky and Wen (1966), is that this unit is not the letter, rather it is the relatively invariant set of correspondences between pronunciation and letter *clusters* when the location of the clusters within a word, with respect to both position (initial, medial, final) and environment (context provided by the other letters in word) are specified (e.g., ban, mat versus bane, mate). Thus work on the fourth stage of development, concerning the use of higher order constraints, overlapped into the third stage.

The results of this line of investigation are absorbing. Initially it was established that nonwords formulated in accord with morphophonemic rules of English spelling (letter

clusters) so as to be pronounceable (e.g., "nop") are perceived more readily than other nonwords formulated so as to be less pronounceable but matched with the pronounceable ones for identity of letters used (e.g., "onp") (Gibson, Pick, Ossei, and Hammond, 1962). That is to say, it was found that Ss as young as first graders were able to make use of such constraints in recognizing the letter composition of nonwords (Gibson, Ossei, and Pick, 1963). In more recent work along this line Gibson, Shuchliff, and Yonas (1966) demonstrated that the presence of some sort of morphophonemic structure, over and above learned spelling-to-sound regularities, is responsible for the relative ease with which Ss perceive the pronounceable words.

The import of this line of work for reading instruction concerns the implication that children can take advantage of both the letter-cluster-to-sound relationships and the inherent structural regularities of English spelling in learning to read. Thus the indication is that instruction designed to emphasize these features of printed language should facilitate the acquisition of reading skills.

To this matter as well, Gibson et al. have devoted considerable effort. At the outset, they reasoned as follows: Since skilled readers are able to take advantage of the structure inherent in English spelling, it ought to be possible to discover the means by which this capability is acquired. The importance of the capability is clear: once the structures have been discovered, their transfer value is potentially very high, thus permitting the new reader to master previously unseen printed words without specific instruction. Experimental results strongly indicate the existence of such rules and yet even skilled readers are unable to state them. Thus it was decided to explore the effects of a learning-set paradigm for instruction, a paradigm that should permit induction and use of regularities without requiring a verbal statement of the regularities.

Gibson, Farber, and Shepela (1967) have reported the results of a pilot study using this approach. The study was conducted with kindergarten and first-grade children, the interest being to determine whether or not such children could be led to make the necessary abstractions from sequences of patterned words and pseudowords. A discrimination

problem method was used initially but proved too difficult for the Ss, confirming the experience of Silberman (1964) with a similar approach. Finally, resort was made to a sorting task procedure for inducing the children to discriminate whether words fit a given pattern (e.g., lack, muck, deck, sock) or not (e.g., lake, much, derk, soak). Each item was typed on a separate card and the cards were presented individually to the S. When a card was presented, the S's task was to place it in one or the other of two categories, positive or negative. A correction procedure was used and the child was permitted to view the last cards placed in both the positive and negative categories while making his next choice. This method proved superior to a simple discrimination method and at least a few children demonstrated acquisition of the intended learning set. Obviously, this research is not sufficiently far along to permit strong inferences about the nature and development of curricular materials for facilitating the acquisition of reading capabilities. But the approach seems to promise some such implications in the finite future.

A related enterprise, also directed at problems attendant to promoting successful acquisition of reading skills, is that under the direction of Levin (1965). Marchbanks and Levin (1965), for example, found that children discriminate among similar words on the basis of initial letter differences whenever possible and ignore other features of the words. The same effect has been confirmed by Samuels and Jeffrey (1966). This, of course, implies that in any discrimination learning procedure, great care must be taken both to construct alternative sets in ways that induce the child to attend to the word features to be learned and to evaluate what the child has learned at the end of training. In another study related to the problem of word identification, Levin and Watson (see Williams, 1965) found that in children, training in variant grapheme-to-phoneme correspondences (one grapheme to two phoneme responses) facilitated acquisition of similar transfer materials more than training in invariant grapheme-to-phoneme (i.e., letter-to-sound) correspondences (one grapheme to one phoneme). Incorporating these two findings, Levin et al. are exploring the effects of various conditions of discrimination learning

on the acquisition of spelling-to-sound correspondence rules.

In a somewhat different vein, Levin and Tuner (1966) have investigated the role of larger-unit language structures on reading performance using as a measure the eye-voice span. The results indicated that the more advanced the reader (whether indexed by his grade level or his reading speed), the greater the tendency to read to the end of major phrase units after illumination is withdrawn. A related study (Weber, 1967) examined oral reading errors made by first-grade children in a classroom setting. Errors were cross-tabulated according to the reading-achievement level of the students and their effect on the grammaticality of the sentence being read. The results revealed a substantially greater sensitivity to grammatical constraints among the good than among the poorer readers. That is to say, of the errors made by the good readers, a large proportion maintained the grammatical integrity of the sentence, and of those that violated grammaticality, a large share were subsequently corrected.

To summarize the results of this sampling of Project Literacy studies, the indication clearly seems to be that skillful reading depends upon knowledge of both lower- and higher-order structures inhering in reading materials. The question of whether or not knowledge of these structures is facilitated more by emphasizing reading-to-speech correspondences than by emphasizing the inherent structure of printed materials (including both morphological and syntactic rules) is still open. The data seem to suggest the validity of the position explicated by Bever and Bower (1966) that it is preferable to encourage the acquisition of visual reading skills over auditory reading skills.

Finally, with regard to the matter of the direct implications of these results and hypotheses for the construction of curricular sequences for reading, it is appropriate once again to reiterate the contrast between educational relevance and contribution to educational change. Without question the work emanating from Project Literacy has substantial relevance for schooling in reading skills. Moreover, much of this work has contributed to knowledge in parent disciplines as well, whether psycholinguistics, the psychology of learning, or, more generally, the

psychology of cognitive development. As yet, however, these lines of research have not progressed far enough to permit firm recommendations for programmatic changes in educational practice. This step remains to be taken and will probably not be taken, nor should it be, until additional basic research is completed. Nevertheless, the direct attack being made by the psychologists involved in Project Literacy upon the problems of optimal instructional conditions as well as upon the basic nature of psychological processes involved in reading acquisition promises to yield information that can indeed be used in effecting propitious changes in educational practice.

This same mode of attack has, of course, been used by other psychologists of cognitive development whose interests lead them into research relevant to reading. Elkind (Elkind, 1965, 1967a, Elkind, Horn, and Schneider, 1965, Elkind, Larsen, and Van Doorninck, 1965), for example, has reported a number of studies examining the relationship between developmental status (defined in Piagetian terms) and reading proficiency. Perceptual decentration (e.g., the ability to reverse figure and ground in perceptual objects) has been shown to relate to reading achievement in children drawn from grade levels two through six (Elkind, Horn, and Schneider, 1965, Elkind, Larsen, and Van Doorninck, 1965). Such results are interpreted within a strongly maturational framework that draws heavily upon notions introduced by Piaget. It is argued that the acquisition of the capability of letter identification is a matter of perceptual decentration rather than a matter of the discrimination of distinctive features. Perceptual decentration is held to come about when the child engages in an underlying process of logical multiplication of, say, the class of all letters with the class of all sounds, yielding all of the possible combinations of letter-to-sound relationships in English spelling. This product forms the basis of the necessary abilities for reading acquisition. It is this underlying capability—logical multiplication of properties of perceptual objects—that is responsible for the observed relationships between performance on figure-ground tasks and reading achievement. Finally, since it is presumed that initial reading depends upon the attainment of such underlying pro-

cesses, and since it is also assumed that these attainments are more heavily determined by maturation than by learning (Elkind, 1967a), the capability of acquiring reading skills is itself held to be determined in large measure by maturational factors.

A position such as that promulgated by Elkind is in no sense incompatible with the evidence available. Indeed it is consistent with evidence in some striking ways. The puzzling property of this kind of position is that it touches down at so few points. Given the wide expanse of the theory and its complexity in terms of numbers of propositions, it might be expected to be vulnerable to data more frequently than it seems to be. Consider, for example, the matter of categorizing figure-ground discriminations as perceptual decentration and the attendant assertion that this same process is involved in the acquisition of letter discrimination. Empirical demonstrations of both these assertions would make the case considerably more convincing. The problem that arises when more empiricism is demanded of the approach is that its maturational component virtually precludes the possibility of obtaining compelling experimental evidence of the usual sort. That is to say, suppose it were decided to test directly the hypothesis that increased skill in perceptual decentration produces increased skill in reading. The direct test would be to increase experimentally decentration capabilities and to observe the effect on, let us say, letter identification. But if change in decentration skill, that is, the development of logical multiplication, comes about largely as a result of maturation, the essential experimental manipulation would be ineffective, it would not be possible to increase decentration experimentally. Thus an adequate test of the hypothesis could not be made.

Obviously, the difficulties involved in evaluating theories having a maturational emphasis is no reason for rejecting them. In fact, as discussed earlier, learning emphases are subject to a complementary indeterminism precisely with respect to the maturational issue. In the present case the issue revolves around the question of whether the development of perceptual decentration in children can be accelerated through instructional procedures of some kind. The learning theorist would take the position that such a

goal could be accomplished, but he is free to conclude that failure to do so is attributable not so much to maturational factors as to insufficient conditions of instruction. On the other hand, success in accomplishing this sort of acceleration would provide evidence inconsistent with the maturational emphasis (see Elkind, 1965, Gibson, 1965b). With regard to education, this sort of dispute can have two fruitful implications. The first is that considerable effort ought to be expended in attempts to facilitate the development of perceptual skills that are presumed necessary for reading competence. The second implication is that methods should be found for presenting reading materials that circumvent the child's maturational deficiency.

Recent work suggests that the initial teaching alphabet (ITA) may provide an instance of this last implication, that is, of accommodating to the child's developmental level by specially designed curricula. Thus before leaving the topic of reading, it is important to consider briefly the relationship between some of the findings and hypotheses emanating from psychological research on basic reading processes and developments in the field of reading instruction *per se*. Specifically, it is well to be aware of the results of studies comparing the relative efficacy of regularized and traditional orthographies for facilitating the acquisition of reading skills. A review of this issue involving comparative studies of traditional orthography (TO) and ITA has recently been published by Downing (1967).

The ITA was designed to promote the acquisition of beginning reading skills in children who do not have the capability of constructing sets of complete letter-to-sound correspondences. By and large, the characters used were chosen to provide a unique correspondence for each of the component sounds in English speech, and the corollary spelling system was designed to take advantage of this property. Elkind's (1965) position leads to the conclusion that children should be able to read more easily in ITA than in TO because the capability of logical multiplication or perceptual decentration is not required. Since there is a different character for each speech sound, it is not necessary for the child to learn variable relationships between graphemes and phonemes. The evidence appears

to be consistent with this position in relatively well-controlled studies comparing the effects of TO and ITA (see Downing, 1967), the acquisition of literacy skills does appear to proceed more rapidly when regularized spelling is used. Does this outcome present a problem for the sort of theory outlined by E. J. Gibson (1965a)? The answer depends upon the results of a distinctive feature analysis of the ITA characters rather than, as suggested by Elkind, Larsen, and Van Doorninck (1965), simply upon the fact that more characters must be discriminated in ITA than in TO. It might turn out to be the case that a distinctive feature analysis of ITA characters would show them to be less confusable and therefore more easily discriminated than TO characters.

Relative to the research of Levin and his associates, the comparisons of ITA and TO raise another question. Beside evaluating the relative ease of reading acquisition in groups instructed by ITA and TO *within* whichever orthographic system instruction was conducted, an assessment was made as well of the relative reading achievement of both groups with TO materials exclusively. That is to say, data are available regarding the performance of ITA-trained children on TO materials at variable intervals after the transition in instruction had been made. Recall that Levin and Watson (see Levin, 1965) found performance on variant paired-associate (PA) transfer tasks to be better after variant PA training than after invariant PA training. In contrast, the results of research by Downing and others on the effects of ITA and TO training in initial reading on subsequent reading achievement in TO shows ITA training, that is, relatively invariant training, to be superior. This result holds despite an initial setback in reading achievement among the members of the ITA groups immediately after the transition to TO materials.

This discrepancy in research outcomes is not a simple one to interpret, the conditions of the two experiments differ in complex ways. However, it is worthwhile to note the possibility that even the best planned and conducted programs in basic research may not produce results that can be directly generalized to instruction without further empirical evaluation.

EARLY PREREQUISITE COMPETENCIES

Whether one chooses to follow out the implications of theories of cognitive development having a maturational emphasis or of those having a learning emphasis, he is led very quickly to a consideration of the requisite capabilities for subsequent development or learning at the earliest of the major educational junctures. Both kinds of theories direct attention to the critical importance for educational development of the child's initial status when he enters school, for the instructional experiences the schools provide presuppose considerable prior learning. Thus it is necessary to specify the capabilities prerequisite for additional progress in the kinds of cognitive development demanded in schooling. Consistent with the intensity of present concern among those working in the field of cognitive development, considerable emphasis will be given to capabilities deemed necessary for a successful transition across the boundary separating formal schooling from prior experience. The focus will be upon the capabilities presumed to result from home, preschool, and kindergarten experiences.

The discussion of capabilities pertinent to the transition to formal schooling will be organized in terms of six general areas of competences: attentional, behavioral control, perceptual, linguistic, learning, and conceptual. Our concern will be to draw upon the work of psychologists in an effort to specify the competence necessary within each of these domains for a child at this level of development. Although our primary focus will be upon children in the chronological age range of 4 to 6 years, we shall find it necessary occasionally to extend our discussion beyond this interval. In the case of each of the varieties of competence distinguished, we will proceed by first describing it, then inquiring about individual differences, and last by considering research relevant to augmenting the competency in children.

Attention

Since instruction is the principal aim of education and since instruction is concerned mainly with arranging environmental conditions conducive to cognitive development, the

capacity of the individual to attend to relevant environmental events is critical for success. It will be recalled that considerable notice is given to matters of arousing and maintaining attention in both types of theories reviewed here. Each considers attention to be absolutely crucial for school success. Hence there is little argument about its importance.

The meaning of attention is a different matter. What is attention? What are its manifestations? What are its determinants? How does it relate to learning and educational development? Clear and complete answers to these questions cannot yet be given. Indeed, despite its obvious importance in cognitive functioning, the topic of attention as such has been dealt with by psychologists mainly in indirect ways. Frontal assaults on the problem are rare even within psychology, and psychological research on attention that focuses on educational relevance is even harder to come by. Some reasons for the paucity of research devoted to attention may be found in peculiarities of the history of theory construction in psychology (see Maltzman, 1967). Other reasons have to do with the incorporation of attentional factors in work on other psychological topics such as motivation, perception, and discrimination learning. Thus at the very outset, it must be said that the entire problem of attention and educational development is badly in need of both theoretical and research effort.

The importance of attention for education is plain enough, whether one means attentiveness or arousal. In the complete absence of attention it is unlikely that any learning would occur. In the presence of reduced attention, learning that does occur is likely to be incidental and consequently quite inefficient. A visit to schools where student achievement is characteristically low will frequently reveal a number of classrooms in which a major portion of the teacher's time is consumed with the effort to simply gain the attention of the students. Noise levels in such rooms are often high, diverse activities are engaged in by the students, and a common focus on the material being presented for learning is scarcely ever observed.

What is attention? Let us begin by thinking of it in terms of the probability that available stimulation will be registered by the indi-

vidual Thus attention is to be thought of in terms of a response of the organism, which may be indexed physiologically in various ways (see Maltzman, 1967) Attention is related to notions of motivation and drive but is not necessarily coincident with them For example, exceptionally high drive has the consequence of interfering with performance on difficult tasks, whereas heightened attention appears to improve performance on such tasks (Belloni, 1964) Nevertheless, at this point in the development of a psychology of attention, it is well to consider a number of related notions—conflict, arousal, curiosity, orienting reflexes, and observing responses—as they pertain to education

Perhaps more than any other single psychologist, Berlyne has systematically examined and investigated the importance of arousal for the occurrence of cognitive activities (1960, 1965) As he points out, the sort of arousal that most often eventuates in *epistemic* behavior (knowledge acquisition) is evoked by conceptual conflict, that is, by a discrepancy between expectation and reality in the form of antagonistic or contradictory beliefs An example of conceptual conflict is provided by the antagonism between the long-held belief that the so-called inert gases are in fact inert and the contradictory observation that under certain conditions they are reactive The notion is closely related to that of equilibrium-disequilibrium in Piaget (see Flavell, 1963) and to that of conflict between representational modes in Bruner's theory of instrumental conceptualism Thus conflict between what the child expects to see, hear, or happen—whether it takes the form of stimulus complexity, novelty (Berlyne, 1958), an encounter with an unanswered question (Berlyne, 1954), or an unexpected physical event (Suchman, 1960)—can provoke attending behavior

At bottom, the attention-producing effects of conflict may partake of the basic processes referred to under the rubric of the orienting reflex (OR) Much of the work on the OR has been carried out in Russia and has been summarized elsewhere (Razran, 1961, Maltzman, 1967) We shall simply note here that the necessary precondition for the OR is stimulus change, that it is respondent in nature, and that heightened ORs can produce better performance on learning tasks Closely

related to the OR is the observing response, an instrumental response, such as a voluntary movement of the eyes, which facilitates stimulus reception Shortly we shall consider ORs again, along with observing responses in connection with the problem of augmenting attention

Individual Differences The comparatively retarded state of theory and research on attention has predictably yielded very little in the way of results and conclusions regarding related individual differences Maltzman (1967) has reported evidence to the effect that individual differences in OR are related to conditionability, "awareness" of contingencies between CS words and semantically related generalization test words, and paired-associate learning efficiency on both easy and difficult lists of PAs There are no data, however, concerning the relationship between strength of ORs and variables such as age, IQ, race, or socioeconomic status Similarly, little is apparently known about the extent and stability of individual differences in observing responses or about the relationship between these and individual differences in other variables Even though there is little doubt that individual differences do exist in the effects of novelty and complexity upon attention, systematic work on these is only barely underway (see Spitz and Hoats, 1961)

Before leaving the topic of individual differences in attention, it is appropriate to mention the attention theory of Zeaman and House (1967, also see House and Zeaman, 1963) In brief, their position is that the observed relationship between individual differences in IQ and in discrimination learning performance is largely ascribable to an attentional factor rather than to differences in rate of learning per se The case made is a persuasive one and finds support in the work of White and Plum (1964), but it provides relatively little educationally useful information about the factors controlling attention, being directed rather at an explanation of variations in learning proficiency

Augmenting Attention The question of how attention may be elicited in children and maintained or controlled thereafter is also largely unanswered There are, however, some data available and some relevant speculations as well

With respect to ORs, the basic condition

for elicitation is stimulus change. It is known that ORs habituate readily, implying that if stimulation is to be attended to it must be varied frequently. This bit of lore does not advance us very far with respect to the educational problem of controlling children's attention, however, for we know little about how to change characteristic individual differences in ORs or, in fact, about how to measure them in any useful way outside the laboratory.

With regard to observing responses and other still higher-level behavioral expressions of attention, the situation is somewhat better. It is common to attack the problem of specifying factors that determine the maintenance of attention by distinguishing between extrinsic and intrinsic reinforcement. Without becoming involved in the definitional tangle that sometimes ensues upon the mention of this distinction, let us specify that by extrinsic reinforcement we shall refer to properties of events that are not inherent in the materials to be learned or attended to, and that by intrinsic reinforcement we mean properties of the materials or stimuli themselves that have the effect of increasing the probability of the behavior in question.

Apparently both kinds of reinforcement can be effective in controlling attention. Fisch and McNamara (1963), for example, have shown that it is possible to control the attention of college students in a perceptual task through the delivery of simple verbal approval. With regard to intrinsic properties of stimulation, the work of Beilyne (1958), Fantz (1961), and Hershenson (1967) shows that properties of visual stimulus materials (although there is still dispute about just what the properties are) control the direction and extent of attention in infants. Comparable research is not available for children of early school age in any substantial quantity. One study reported by Cantor, Cantor, and Ditricks (1963) indicates that complexity of stimuli controls attention in preschool-age children. Other studies (see Cantor, 1963) suggest that novelty or unfamiliarity as well as complexity exert control over children's attention.

In a different approach to the problem of attention, Hagen (1967) has investigated developmentally the effects of vigilance distractors on both central and incidental perfor-

mance on a memory task. Drawing upon an information-processing model of attention and memory (Maccoby and Hagen, 1965), Hagen hypothesized that older children to a greater degree than younger children would be able to attend to relevant stimulus features in the presence of distraction. The results, however, showed a clear age effect across grades 1, 3, 5, and 7 but, at all ages, attention was poorer with distraction conditions.

Clearly, with regard to education, at least three kinds of developmental information are urgently needed about attentional processes. The first need is for research that isolates the sources and provides a means for measuring individual differences in attention, that is, in intensity of ORs, latency of observing responses, duration of attention, and resistance to distraction. The second sort of data concerns the problem of specifying stimulus properties that gain and control attention, especially across the preschool and primary school age ranges. Third, it is important to construct and evaluate methods for training attentiveness, whether they involve extrinsic or intrinsic means of reinforcement. Without substantial additional work on these problems, the psychology of cognitive development has only minimal contributions to make to education with regard to the truly significant task of gaining and controlling attention.

Behavioral Tempo

In addition to attention competence, a child needs to be capable of modulating his behavior, his overt responses, if he is to maximize his learning. The three different but related kinds of behavioral control important to successful schooling may be distinguished: bringing overt responses under the control of verbal instructions emanating from another person, the capability of controlling behavioral responses by giving verbal instructions to oneself, and the delay of overt responding to provide time for internal scanning and processing of information.

Recent research by psychologists of cognitive development is relevant to each of these areas of behavioral control. Each has been shown to change as a function of age during the early childhood years. Consider first the matter of bringing motor response under external verbal control. A series of experiments reported by Lunia (1961) indicates

that this capability of subjugating motor responses to the control of outside verbal instructions develops rather slowly in the child between the ages of 1½ and 6 years. About the best kind of external control that was observed in children up to the age of 4½ to 5 years consisted of verbal utterances being effective only as signals, not as directions. Thus the utterance "Press!" (a rubber bulb) is effective in instigating a response in the younger child, but "Don't press!" is not effective in terminating responding. In contrast, children in the older age range are capable of abiding by the semantic instructions contained in verbal utterances. They can, for example, on the basis of prior instructions, withhold responses until the onset of some exteroceptive signal and cease responding in accord with such instructions as well.

Similarly, with regard to the capability of regulating overt responses by the child's own speech, verbal control in terms of its semantic content emerges later than in terms of its initiatory signal properties. Up to age 4½, the child's self-instruction "Press!" is effective in instigating a response, but "Don't press!" is not effective in terminating responding. It is only later that the semantic content of the child's own speech comes to control and direct behavior. In connection with a very different task, discrimination learning, a similar change has been reported in the efficacy of self-originating verbalizations for controlling overt responses (Kendler and Kendler, 1962). The Kendlers report their observation that 4-year-olds frequently utter the verbal label of the correct choice in a discrimination task while simultaneously making the incorrect choice as indexed by their motor responses, whereas by age 7 years the two modes of response are consistent.

Finally, a series of studies under the direction of Kagan (1965) demonstrates a distinct, generalized, developmental trend in the direction of an increased tendency to delay responding in a variety of tasks. This tendency has been shown to be sufficiently general to be identified as a trait dimension, impulsivity-reflectivity, contrasting a propensity for offering responses at the first opportunity with a propensity for withholding responses long enough to permit an adequate evaluation of their validity.

Typically, a child's tendency toward an

impulsive or a reflective style is measured in terms of his performance on one or another of several tasks that have in common the property that answers to each of their items must be made in the face of considerable degrees of uncertainty. The major index of impulsivity-reflectivity is response latency. Each of the tests used has been demonstrated to have a moderate degree of reliability across time, or the trait has been shown to have a moderate degree of stability over time ($r_s = .60$, Kagan, 1965). Furthermore, the degree of relationship across tasks has been satisfactorily high. Developmentally, response latencies on such tasks have been shown to increase with age, at least as evaluated by cross-sectional research, from first through eighth-grade levels.

Finally, the dimension of impulsivity-reflectivity has been shown to relate to measures of performance adequacy on the index tasks and on other tasks. That is to say, the tests used to measure response latency also yield error measures. The general result is that latency and errors correlate negatively so that reflectivity seems to be associated with a tendency for the first response to be a correct one. It has also been shown that latency on the defining tests correlates negatively in serial learning tasks with the frequency of extralist intrusions, that is, of overt erroneous responses not contained in the serial list. Furthermore, errors in word recognition among first-graders have been shown to correlate with impulsivity so that relatively reflective children, especially among those having high verbal ability as measured by WISC performance, make fewer reading errors than impulsive children.

The work of Luria and that of Kagan and his associates are of impressive relevance to educational practice, especially as regards the early years of formal schooling. Luria's work shows that a child's ability to be controlled by the verbal utterances of the teacher and to control his own behavior through self-instruction and verbal monitoring cannot be assumed to be intact when he enters the schoolroom for the first time. In terms of present school practice, these abilities are of considerable consequence. Tasks are set for children almost entirely in terms of teachers' verbal instructions. Task persistence, due to the relatively large number of children in

classrooms, is less a function of the teacher's continuing verbalizations to individual children than of the child's own ability to extend his efforts over time in response to his own verbal instructions whether they are covert or overt

The results of both lines of investigation, the development of the regulatory function of speech and the development of conceptual tempo, indicate the necessity for modifying the classification categories used by schoolmen to identify children. In many cases a child's failure in the early school years may be attributable to slower than average development of the abilities to control behavior through verbalization and to withhold responses long enough to assess their validity. At the early stages of schooling, children who are impulsive and who cannot seem to follow instructions or persist on tasks without constant supervision may be classified too readily as less bright and less promising than others. Furthermore, they may be subjected to punishment for their behaviors, resulting in apathy, anxiety, or hostility to schooling and to intellectual activities, rather than being provided with training in these subskills that appear to be necessary for school success.

Despite the fact that a strong case can be made for the urgency of incorporating the information yielded by the theorizing and the research of Kagan and of Luria into early childhood schooling procedures, a clear recommendation to this effect cannot be made. Research information is not yet sufficient, nor are the means for accomplishing incorporation yet available in a form appropriate for school use. In the case of impulsivity-effectivity, for example, it is not clear to what extent school-related cognitive abilities are *determined* by tendencies toward one or another of these response dispositions, nor are the instruments necessary for locating individual children along the dimension fully enough developed to permit their use as diagnostic tools. By way of examining these qualifications more closely, let us turn to a consideration of the topic of individual differences in connection with behavioral tempo and control.

Individual Differences The exploration of individual differences in the role of speech as a behavior regulator has barely begun. The investigations reported by Luria indicate

clearly that the efficacy of speech regulation varies substantially as a function of age, and this information is useful for alerting the schoolman to the fact that this capability cannot be assumed in all children of all ages. But the information is minimal since for the purposes of educational practice, it is essential to know how differences in speech regulation relate to other differences among individuals *within* the same chronological age range. For example, it seems likely that ethnic group membership or socioeconomic status might bear substantial relationships to differences in the ability to bring motor behavior under verbal control. Also, we know virtually nothing about the relationship between early childhood differences in the capacity for verbal control and broader intellectual capacities such as intelligence test performance during the same period and at later ages.

Beyond the problems presented by the absence of basic information about such individual differences, another major obstacle to educational use of the notion of verbal control is the lack of a reliable method for classifying children with regard to this capability. The need here is for a measuring instrument that is feasible for in-school use. As we saw to be the case with the orienting reflex, the operations for measuring the extent of development of speech as a mechanism of behavior regulation are appropriate for laboratory use only. It is inconceivable that children could be routinely tested using these methods. Thus a massive job of test construction remains to be done.

The situation with respect to the dimension of impulsivity-effectivity is somewhat better. The path is shorter from presently available measuring instruments to instruments appropriate for school use than is the case for general verbal control. Kagan and his associates have already demonstrated the existence of reliable individual differences in the disposition for impulsive responding, although a variety of relationships between impulsivity and other subject characteristics remain to be explored. We already know that impulsivity decreases with age, the correlation between impulsivity and verbal ability is relatively low, there are relatively unsystematic sex differences in impulsivity, and the degree of relationship between im-

pulsivity and reading proficiency in young children is negative and moderately high (Kagan, 1965). What we do not know is the nature of relationships between impulsivity-reflectivity and ethnic and socioeconomic differences.

Thus the principal needs are two: one for a single measuring instrument to detect individual differences in impulsivity, which can be used in school settings, and one for additional information about relationships between impulsivity-reflectivity and other subject variables.

Indeed, in general, the means presently available to schoolmen for diagnosing children relative to difficulties in educational development are painfully meager. Psychological research makes it clear that performance on intellectual tasks such as reading is a function of more factors than the IQ and the extent of brain damage (see Kagan, 1965) along with vaguely defined motivational differences. Schoolmen agree that this is the case, but the techniques available to them for classifying children do not permit this belief to exert a systematic effect on practice. Indeed one of the reasons for the strength of anti-testing sentiment, at least as it exists in some quarters, may well be that testing programs are not comprehensive enough rather than that they are too pervasive. The curricular consequences of the narrow range of available diagnostic techniques are that effective programs for dealing with individual differences cannot be developed.

Facilitating the Emergence of Verbal Control and Reflectivity. The task of facilitating the acquisition or emergence of competencies believed to underlie successful school performance is of substantial significance for two purposes. The first, and most obvious, is that the effort to facilitate development coincides precisely with the goal of education. The purpose of instruction, after all, is to promote intellectual development beyond the levels possible in its absence. Discovering means for facilitating the acquisition of basic competencies, then, is central for the educational enterprise in its effort to maximize the positive effects of schooling on individuals. The second reason for dealing with the question of means for effecting facilitation is that when such efforts are successful, a methodology becomes available for ascertaining whether

or not a competency hypothesized to be a determinant of school success does, in fact, contribute to observed variations in school learning. For example, if an effective program were found to install prematurely in children the capability of verbal control of behavior, it could then be ascertained experimentally whether or not such control is related to success in early school tasks.

With regard to verbal control, Luria (1961) has reported an instance of a limited but successful technique for advancing its emergence. The procedure essentially consists of first instituting conditions of nonverbal control over the same behaviors later to be brought under verbal control, and only afterward transferring control to conditions of verbalization. In children of very early ages, 2 to 3 years old, it has been possible to bring bulb-squeezing behavior under at least minimal verbal control by first training them to make overt motor responses in a sequence that is later signalled by the verbalizations. Bruner (1966a) makes much of this technique of sequencing enactive conditions of behavior prior to imposing symbolic or verbal conditions, pointing out that its success is consistence with the tenets of instrumental conceptualism. Clearly, it is a method of facilitation worth more extensive application and evaluation.

Kagan (Kagan, Pearson, and Welch, 1966) has undertaken to explore the possibilities of changing first-grade children's conceptual tempo in the direction of greater reflectivity, that is, longer response latencies. Apart from manipulations, which proved to have little effect, only emphasizing the similarity between the subject and the trainer, the training consisted of three sessions in each of which individual children were asked to work on three different tasks, a haptic-visual matching task, a design matching task, and a test of inductive reasoning. With respect to all of the items on the three tasks, the training simply involved instructing the child not to offer an answer until after a short (10 to 15 second) delay interval had elapsed. Both before and after training, the Matching Familiar Figures (MFF) Test and the Picture Completion Reasoning Test (PCRT) were administered to the children. Each test yielded two scores: response latency and number of errors. The results showed that

the experimental treatment effected changes in impulsive children such that their response latencies on MFF items were significantly longer than those of untrained impulsive children and no shorter than untrained reflective children. Comparable results for PCRT items were not significant.

This experiment demonstrates that it is possible to make short-term, specific modifications in impulsivity, that is, to facilitate the emergence of reflectivity. With respect to the question of the status of reflectivity as a determinant of successful performance on intellectual tasks, however, the experiment is inconclusive. That is to say, despite the changes in response latency produced by training, no significant changes were effected in error frequency. This kind of null result cannot be construed as evidence that reflectivity does not determine quality of performance, but neither does it lend support to the assertion that it is such a determinant. Obviously, then, improvements in the efficacy of training procedures must be made in an effort to affect not only response latencies on a single measure but on many related indices and to affect as well the quality of performance on relevant intellectual tasks. For if reflectivity training can serve only to slow behavioral tempo and not to modify other performances, its educational relevance as a means for effecting change would be questionable.

Even given such an unhappy future conclusion, the utility of the reflectivity-impulsivity dimension for classifying children might still be considerable. The detection of basic dimensions of cognitive style is of no small importance for education, even when such dispositional factors are relatively impervious to modification. For the availability of the dimension as a means of classification makes it possible to design educational programs in such a way as to take account of this source of individual differences and to provide methods for reducing the probability that such differences will obstruct educational development.

Perception

The capacity for perceptual achievements, along with those of attention and behavioral control, is a necessary precondition for successful school learning. Of all the perceptual

modalities, the visual and the auditory are perhaps the most important for schooling because most instructional information is presented in these modes. Since White noted that "The literature on perception in childhood is scant" (1965, p. 201), the situation has improved somewhat and part of the improvement has been in research relevant to education. We have already discussed much of this in connection with the topic of reading. In that discussion, however, we were concerned more with matters of perceptual learning and perceptual discrimination than with phenomena that are purely perceptual in nature and so it must be here. In terms of schooling processes, the major importance of perception has to do with the capacities for learning and discrimination of materials presented in instructional communications.

Gibson (in press) has made an impressive case for the general implications of perceptual learning for education, very much in the manner that we have reviewed them in connection with the acquisition of reading skills. With regard to the question of what is learned through perceptual processes, Gibson's position is that there are two answers. Early in the process of acquiring reading skills, the distinctive features of letters are differentiated. Later in the process, the content of learning consists of acquiring the invariants of higher order structures such as those yielded by the linguist's analysis of morphophonemic and syntactic rules. One of the implications of this kind of view is that the skills and abilities necessary for successful performance at one stage of reading competence are not the same as at another.

This last implication is consistent with results reported by Elkind (1965) of a factor analytic solution of correlational data relating reading performance to other variables. The results apparently showed that a different factor structure emerges for novice than for skilled readers. Elkind's approach to reading is also a perceptual one, informed, as we noted earlier, by Piagetian theory. The kind of perceptual approach, however, is quite different than that espoused by Gibson. One crucial difference is that Elkind's theory of perceptual development rests on maturational assumptions about the growth of conceptual structures that are prerequisite to successful reading performance. In brief,

the necessary structure in question here is the internalization of motor schema and their transformation into operational structures permitting the manipulation of properties of stimuli as is necessary for the carrying out of logical multiplication. Another variant on the schema approach to perception has been provided by Liberman (1957) in an articulation theory of speech perception and discrimination. Roughly, the theory holds that incoming speech signals are identified by matching to articulatory schema built up out of the sequences of movement used in speech production.

Whichever of these major points of view about perceptual development is adopted, they lead to a focus upon the conditions whereby the child becomes capable of identifying and distinguishing among perceptual objects. And it is precisely this capacity that is so important in connection with school learning. The child must be able to, or at least be capable of learning to, identify and distinguish among perceptual events.

A third major theory of how this capability is acquired can be characterized as a response theory. The notion is that perceptual objects or stimuli come to be distinguishable by virtue of the fact that the individual makes differential responses to them. Without entering the controversy over explanations of the "acquired distinctiveness of cues" (Smith and Goss, 1955, Spiker, 1956, Cantor, 1965) it is possible to point out that the learning of verbal responses to perceptual events does seem to facilitate their discrimination (e.g., learning distinctive nonsense-syllable responses to lights of different hue, Reese, 1961).

By way of exploring the implications for education of work in the area of perceptual development let us turn first to a discussion of individual differences and then to the problem of augmenting perceptual development.

Individual Differences. Methods for identifying individual differences in perceptual competence are available. The error scores on the Matching Familiar Figures (MFF) Test (Kagan, 1965) are an appropriate example in the visual mode and, as we have seen, perceptual competence as so defined does increase with age. Kagan (1965) has also reported data indicating a moderately low but statistically reliable relationship between

WISC verbal skills and error scores in visual discrimination in MFF (median $r = -.28$). Covington (1967b), using the Perceptual Discrimination Subtest of the Primary Mental Abilities (PMA) Examination, found upper-class kindergarten children to be significantly superior to lower-class kindergarten children. Both of these measuring instruments, the MFF and the PMA, are, of course, appropriate for school use and could be administered with profit to identify children who are in need of experiences designed to improve their capacity for discriminating among stimulus materials.

With regard to auditory discrimination, much has been made recently of the possibility that lower-class children are considerably disadvantaged in their opportunities for acquiring this capacity (Hunt, 1961, Bloom, Davis, and Hess, 1965, Deutsch et al., 1967). The hypothesis is a simple one. The noise level in low-SES homes is presumed to be exceedingly high, thus providing nonoptimal conditions for perceptual learning. The excessive noise level in such homes is supposed to interfere most severely with the acquisition of capacities for discriminating speech events and for segmenting utterances. These conditions are presumed to contribute to a general language deficiency in low-SES children and to make more difficult the task of learning to read as well as that of learning to register accurately verbal communications from teachers.

In view of the importance attached to auditory discrimination as a correlate of social class differences in more general varieties of intellectual development, it is unfortunate that so few measuring instruments have been developed for investigating the hypothesis.

Perhaps the most used index of capacity for auditory discrimination is the Wepman Auditory Discrimination Test. The test is administered individually and consists of the oral presentation of 40 pairs of words. The Ss task is to indicate for each pair whether they are the same or different. Ten of the pairs are identities and the other 30 are different, differing in either initial or terminal phoneme. The Wepman Test has been given considerable use in a series of studies conducted by Deutsch and his associates (see Deutsch, 1967a, Deutsch, Levinson, Brown, and Pei-

sach, 1967, Katz, 1967, Katz and Deutsch, 1967) The general results of these investigations may be summarized as indicating that there is a relationship between Wepman performance and age, Thorndike-Loefer IQ, and reading ability The correlation between Wepman performance and reading ability was observed in lower-SES Ss and appeared stronger at earlier (second-grade) than later (sixth-grade) ages As nearly as can be determined, however, the major component of the hypothesis relating school success to SES through the mediator of auditory discrimination ability was not supported That is, the correlation between SES and Wepman performance was negligible in both a first- and a fifth-grade sample Although this evidence goes against the assumption that perceptual capabilities in the auditory mode are deficient in low-SES children, the design may not have been adequate to reveal these Apparently, a more thoroughgoing study of the issue is now in progress (C Deutsch, 1967b) Nevertheless, other data already available suggest that the outcome is doubtful Stern and Rabbitt (1966) administered the Wepman and a variant of it, in which the items were nonsense words, to upper- and lower-status children and obtained equivocal results no clear and systematic difference was found favoring the upper-status groups Even when reliable SES differences in Wepman performance have been obtained (see, e.g., Clark and Richards, 1966), the results must be interpreted with caution, for the question remains unanswered whether the inferior performance of low-SES children is due to deficiencies in discrimination or to the meaning such children attach to the response terms "same" and "different" In sum, although auditory discrimination ability does appear to be related to reading task performance, there is no persuasive evidence that it mediates SES differences in reading ability

Educational needs demand both more research in the area of the development of perceptual abilities relevant to education and the construction of instruments for indexing these abilities reliably in children

Augmenting Perceptual Development A variety of attempts to facilitate the development of perceptual abilities has been reported All of these have relevance for educational practice but all are, at this point, still in the

nature of pilot programs, whether they be long- or short-term ones

We have already covered much of the available research on facilitating perceptual abilities as they relate to reading from the viewpoint of perceptual learning One other demonstration guided by this theoretical approach should be mentioned, namely, that of J J Gibson (Gibson, Kennedy, and Toleno, 1967) The idea was to explore the possibility of leading young children to overcome the bent-stick illusion, that is, the illusion that a straight stick bends at the air-water interface By an ingenious use of materials and by implementing a key component of perceptual learning theory, some children were indeed induced to discover that the phenomenon of a bent stick, half in and half out of the water, indicates that the stick is in fact straight As the theory suggests, perceptual learning consists of an appreciation of invariance over transformations and one way of inducing invariance is to view perceptual events from multiple perspectives This is precisely what Gibson's Ss were led to do, and for at least some of them the procedure was successful

One of the appealing features of the entire approach of the perceptual learning theorists to problems of perceptual development consists of their emphasis upon experience with the physical world, in contrast, let us say, to experience with symbolic representations of that world, as a major avenue of education The assumption seems to be that experience with primary objects and events is the basic precondition for the success of later learning about these objects and events There is in this view no argument against the notion that much of this kind of learning, if it is ever to have utility beyond itself, must eventually be represented symbolically, to permit manipulation by abstract operations of thought But the implication is that fruitful learning begins with concrete experience The notion is not unique to Gibsonian theory It is found as well in the theorizing and in the research of Piaget (see Flavell, 1963, Bruner, 1966b, Gagné, 1965a) Piaget and Bruner, in fact, might argue that learning, if it is to be successful, *must* begin with concrete experience

In a somewhat different vein, some of the research of Elkind (Elkind, Laisen, and Van Doorninck, 1965) offers an example of the

possible benefits of training in advancing perceptual development. These investigators, you will recall, were concerned with perceptual decentiation in young children, specifically with the ability of such children to perceive figure-ground reversals in viewing ambiguous drawings. Besides the results already reviewed in connection with their relationship to reading performance, the results of training in the perception of such reversals indicated that significant short-term gains could be brought about by a masking method. The method involved essentially forcing the perception of the nonpreferred figures in a series of ambiguous drawings through the technique of masking the preferred figure by covering it with a template. The success of the training, in fact, provides a real, though minor, contradiction to the notion that the attainment of perceptual decentiation as here defined is entirely a matter of maturation.

Longer term efforts that have been designed within a Piagetian framework (Gray, 1966) should eventually provide additional evidence with regard to the maturational issue. More important for educational practice, they will produce evidence about the effects that can be induced in preschool age children through this approach.

Again with regard to competence in visual discrimination, the study of Covington (1967b) mentioned earlier demonstrates the facilitory effect of simple exposure to the materials to be discriminated. Between the pretest and posttest administrations of the PMA items, experimental groups of both upper- and lower-status kindergarten children were exposed daily to each of the stem figures from all the PMA items in the criterion test. Only the stem from each item was exposed and only for a total of 5 seconds a day per item for 14 days. The two control groups received similar treatment except that the content of the training items was not drawn from the PMA subtest. Significant pretest to posttest gains were reported for both the low- and high-status groups but only in the low-status group was the gain due to treatment greater than that observed in the corresponding control group. Furthermore, there was a significant interaction such that the low-status children gained more from exposure to the test items than did the high-status children. The implication of this study is that the task

of augmenting the ability to make specific visual discriminations in lower-status children is in no sense an insurmountable one. Indeed, the results suggest that children deficient in such a capability can be detected and successfully trained within a school situation. The results of the Covington experiment warrant considerable additional research to provide answers to questions regarding the generalization of such training to other tasks as a function of SES and of age and regarding the effect of successful training in visual discrimination among low-SES groups on their performance in other tasks in which the same materials are used.

Clearly in the limited instances reviewed, sufficient success has been achieved in efforts to augment quite specific aspects of perceptual development to suggest that more systematic and more long-term intervention attempts might be worthwhile. Some kinds of perceptual competence appear to yield more readily to facilitory intervention than others [cf. the ease of producing change in the Covington experiment with the difficulties reported by Gibson, Farber, and Shepela (1967) in inducing a discrimination set with respect to readinglike materials]. It is equally clear that research designed to explore factorially the effects on the acquisition of various perceptual skills produced by type of intervention, age of intervention, and individual differences in presenting status is required before clear recommendations can be made for educational practice. Such research is of practical importance, to be sure, but it is of theoretical importance as well. It could be designed to shed light on both the contributions of maturational components and experiential components to the development of competencies in specific skills.

Language

Language competence is believed to figure importantly in school success for a variety of reasons. Three functions may be distinguished that are performed by language in connection with education (see Deutsch, Levinson, Brown, and Peisach, 1967). The first is that linguistic competence at the phonological, syntactic, and semantic levels is necessary so that a child can register and comprehend the communications directed toward him in the process of schooling, whether they are oral or

written. Second, a child's success in performing the intellectual tasks set for him by the school is more frequently judged by his written and oral linguistic productions than by any other means. Finally, evidence continues to grow in support of the proposition that language affects extralinguistic cognitive processes such as perceptual discrimination and behavior control, in critical ways (see Elvin-Tripp and Slobin, 1966, Elvin and Miller, 1963) even though it is not a necessary condition for general intellectual competence (Furth, 1964). As the latter function of language has been dealt with in connection with the topics of reading and of perception and will be considered again in relation to learning and conceptual competencies, the present discussion will be confined to the first two functions.

Since the development of linguistic competence with respect to both comprehension and production has been ably discussed both in this book (see chapter by McNeill) and elsewhere (see, e.g., Elvin and Miller, 1963), brief comment will suffice here. In children whose cultural and social backgrounds are consistent with those typically assumed in the present design of schooling, both phonological and syntactic development are reasonably far advanced by the age of school entrance. Thus the areas of language development having the greatest relevance for education are semantic development, individual differences in phonological, syntactic, and semantic development, and means for advancing language development in those children who, for whatever reason, are retarded.

Individual Differences As in most areas of cognitive functioning, individual differences in rate of language development are pervasive. Apart from cases of exceptional abnormality, however, the final levels of linguistic attainment, in the linguist's sense of underlying competence, are reasonably equivalent across individuals. Rate of development does vary across individuals as revealed by the average length of utterances in small-scale, intensive studies (e.g., Brown and Bellugi, 1964), by larger-scale psychometric studies of the sort carried out with the Illinois Test of Psycholinguistic Abilities (ITPA) (McCarthy and Kulk, 1961, 1963), and by larger-scale studies of speech samples in which measures of type-token ratios and

vocabulary size are obtained (Loban, 1965).

A singular problem is presented by the decision of how to measure or index a child's status with respect to language development. Language is a complex function and there is little doubt that many of its facets are worth assessing across individuals: receptive and productive phonological competence, receptive and productive syntactic competence, and receptive and productive semantic competence. The ITPA represents an attempt to provide an instrument capable of making comprehensive assessments of language development and of permitting selective diagnosis of language deficiencies. Its strength lies in the simple fact that it has been developed, standardized, and used. Nothing else has even this much to offer. There are, however, two limitations inherent in the ITPA.

The first limitation concerns the theory that guided and informed the construction of the test, which was promulgated by Osgood (1963). Saying this is not at all to fault the test or the theory but to point out that of the two major theoretical positions currently available regarding the skills or competencies that are central to language development, the test represents adequately only Osgood's. Even to one only mildly acquainted with modern linguistic theory, an inspection of the nine subtests on the ITPA evokes surprise at the paucity of attention given to strictly linguistic matters. Specifically, what the instrument assesses may be described as verbal vocabulary, pictorial vocabulary, verbal analogies, pictorial similarity, object description, knowledge of the function of objects, knowledge of inflections, digit-span, and memory for the arrangement of visual stimuli. With regard to the second of these major theoretical positions, there is no psychometrically standardized instrument available to assess language development from the point of view of that large body of theorists and investigators who espouse some version of the kind of linguistics so imposingly explicated by Chomsky (1957, 1965). Thus there is need for a test capable of assessing the components of language development from this alternative point of view. The absence of such an instrument from the psychometric scene is not due to a lack of appropriate tasks with which to compose it. Brief reflection yields a number of possibilities, drawn mainly from the literature of experi-

mental research on psycholinguistics (e.g., Berko, 1958, Slobin, 1966, Ammon, 1967)

The second limitation of ITPA with respect to the study of individual differences concerns the overlap of the test with commonly used tests of intelligence. Suppose one wanted to evaluate the relationship between language development and intelligence. The fact is that ITPA would not be a good instrument for achieving the goal since of its nine subtests, six have virtually direct analogues in the Stanford-Binet and/or the WISC. Accordingly, a relationship would almost certainly be detected between language development and intelligence. This problem is not unique to ITPA. Virtually any attempt to answer the IQ-language development question is beset with problems since the most commonly used intelligence tests include a number of scales that measure verbal skills.

Perhaps the most lively topic of individual-differences speculation and research relative to language is that which concerns variance associated with social class or ethnic group membership. Many of those concerned with the poor school performance of children from culturally disadvantaged homes attribute a large measure of observed deficiencies in such children to language differences relative to the dominant culture (Bereiter and Englemann, 1966, Bernstein, 1961, 1962, 1964a, 1964b, Bloom, Davis, and Hess, 1965, Deutsch, 1963, 1967). Available data on this issue are meager, available speculation is plentiful. Bernstein (1961, 1962, 1964a, 1964b) has provided both and has well instructed us in the distinction between restricted and elaborated linguistic codes. The distinction may be understood best from the viewpoint of a listener. If the speaker is using a restricted code, the structure of the message he utters will be characterized by one or another of a small number of syntactic alternatives. Thus from the listener's point of view, the structure of the message is highly predictable. In contrast, the structure of a message uttered by a speaker using an elaborated code is highly unpredictable. In an elaborated code, the number of available syntactic alternatives is large. Because of this property, an elaborated code permits the precise expression of discrete intent solely within the verbal channel. In a restricted code, however, the communication of precise meaning is not

possible. Bernstein's hypothesis is that persons in all social strata have available to them the restricted codes of their social group. But higher-strata members are also capable of using elaborated codes, whereas working-class members, because of their early experience in a restricted linguistic environment, have not acquired the capacity for using such codes. Since elaborated codes are well-fitted for communications related to academic matters and restricted codes are not, working-class children are severely disadvantaged in the face of school-learning tasks.

Loban (1965) has collected extensive data relevant to language development as a function of age, social class, and ethnicity. Although his study was not experimental in design, it provides information of substantive importance, much of which is consistent with Bernstein's contentions. For example, in both low- and middle-SES samples, complexity of speech, as measured by the average number of words per communication, increases with chronological age. But the speech of middle-SES subjects is consistently more complex than that of low-SES subjects and the magnitude of the difference increases with age. Moreover, the speech of middle-SES subjects is more flexible than that of low-SES subjects, as measured by the variety of structures used in nominalization (nouns, pronouns, noun clauses, infinitives, verbals) and by the frequency of use of subordination (dependent clauses, participial and infinitive phrases, gerunds, and appositives). These data support Bernstein's hypothesis regarding deficiencies in the use of elaborated codes by members of the lower socioeconomic classes.

A promising line of research on this problem is that under the direction of Labov (Labov and Cohen, 1967). This mode of attack consists of the elicitation of spontaneous and imitative speech from Negro Ss living in New York City and the subsequent linguistic analysis of these productions in an effort to formulate the phonological and syntactic rules of nonstandard English speech in the populations sampled. Their Ss have been sampled according to a stratified model designed to permit comparisons among males and females, older and younger Ss, middle- and working-class Ss, those raised in the north versus those raised in the south. Although preliminary in nature, their results at this

point suggest that observable differences between the "non-standard vernacular of the urban ghettos" and standard English are "greater on the surface than in the underlying grammatical structure" (Labov and Cohen, 1967, p. 66) and that these Ss are capable of perceiving, understanding, and reproducing the meaning of many standard English utterances even though they themselves cannot produce them.

The work of Labov cannot be construed as contradictory to the contention of Bernstein and others that lower-class deficiencies in the use of elaborated codes impairs intellectual abilities that relate to school performance. This remains a very lively hypothesis. Nevertheless, it still awaits experimental validation.

Facilitation of Language Development

Two instructive attempts to facilitate language development are those of Cazden (1965, 1967) and of Bereiter and Englemann (1966). At its inception, Cazden's work was guided by the hypothesis that grammatical development was assisted by contingencies between children's utterances and adult expansions of these into acceptable standard English form. Brown and Bellugi (1964) observed that mothers frequently imitate the young child's utterances. This imitation, however, is not exact. Indeed, the mother's utterance characteristically expands the child's into standard English (e.g., child "Throw Daddy" Mother "Throw it to Daddy"). Brown and Bellugi (1964) noted the possibility that these processes of expansion might facilitate the child's acquisition of syntax. In both an experimental study with children aged 28 to 38 months and in later observational studies, however, Cazden (1967) did not find support for this hypothesis. Instead, the indication seems to be that considerable assistance to language development is provided by the availability to the child of various syntactic components in adult usage, that is, adult "modeling" seems to be of more help to the child than contingent expansions.

The efforts of Bereiter and Englemann (1966) are impressive for their comprehensiveness, their thoroughgoing dedication to the efficacy of overt practice in the performances to be acquired, and in the results achieved. There was a programmatic attempt to improve the intellectual abilities of disadvantaged preschool-age children. In the

initial study, 15 children were subjected to a 9-month "academic" preschool program in which they were given direct training in speech, arithmetic, and reading skills. For example, the children were required to repeat in unison the utterances of a teacher until they could use them with considerable facility. The results of the training were an increase in average IQ from 93 to 100, performance on the ITPA at or above grade level, and performance on the reading and arithmetic subtests of the Wide-Range Achievement Test sufficient to place the children in the category of those ready to enter the first grade. These results must be evaluated with respect to the usual status of children drawn from equivalent populations, who at comparable ages are substantially retarded on these measures. Even though an adequate control group was not used in evaluating the success of this program, the method seems promising. Furthermore, the program was conducted in a classroom setting, making the techniques used almost directly available for adoption by schoolmen.

Unfortunately, the absence of a control group and the very comprehensiveness of the program create difficulties in construing the results as evidence relevant to the issue of whether it is, in fact, a language-centered deficiency that determines the poor school performance of lower-class children. This issue is sufficiently important to command experimental verification.

Learning and Conceptual Competencies

The combination of learning and conceptual competence under a single heading deserves brief comment. The division between any pair of topics covered here, language and perception, perception and learning, etc., is somewhat arbitrary but is made for convenience of exposition and in order to follow conventions of demarcation widely shared among psychologists. Learning, however, is something of an anomaly among the other topics since it can be applied to each of them. It is, in fact, common to refer to perceptual learning, conceptual learning, learning of language (although this is presently out of fashion), learning of behavioral self-control. In other sense it is also true that perception, attention, and so on, are prerequisites for some kinds of learning. All of this is to say that there are *varieties* of

learning which can be distinguished from one another in various ways (cf Gagné, 1965a, with Melton, 1964) With regard to educational relevance, some of these varieties can conveniently be discussed together because of their apparent centrality for the attainment of educational objectives It is to such varieties that we refer here

Recent developments in research on learning reveal an increasing emphasis on the role of nonrote processes, especially as they contribute to successful or efficient learning Our discussion of learning will focus upon such processes and our discussion of conceptual processes will likewise center upon those presumed to underlie successful conceptual behavior First, however, let us sketch briefly some of the known facts about developmental changes in learning and conceptual behaviors

The general fact about learning proficiency—as measured by performance on laboratory tasks such as those of discrimination learning, serial learning, and paired-associate (PA) learning—when plotted as a function of age, is that it improves It is of pronounced importance to determine whether this improvement consists of a simple, linear accretion of skills that make for progressively greater efficiency or if it consists in one or more relatively discrete shifts in underlying processes Before considering this issue and its implications, consider the bare curve of improvement for some selected learning tasks

Simple discrimination learning improves in children, at least up to ages 5 to 7 years (Stevenson, Iscoe, and McConnell, 1955, Wen and Stevenson, 1959) and, in some cases, even up to age 12 (Katz, 1967) Performance on both serial and PA learning tasks improves considerably across the age range 5 to 14 years, although serial learning performance appears to asymptote earlier than PA performance (Jensen and Rohwer, 1965) With regard to more complex forms of concept learning, Piaget and his associates have found considerable increases in the ability to handle problems of conservation, transitivity, and classification over the age range from 3 or 4 to 11 (see Wallach, 1963)

So much for the basic facts indicating improvement with age What are some of the component processes that may be presumed to account for the increased facility with which children perform on these varieties of

learning tasks? With regard to discrimination learning, the answer is ambiguous Gibson's position as we have already noted would lead to the presumption that children increasingly are able to differentiate stimuli in terms of their distinctive features An alternative position is that children come increasingly to attach distinctive responses to individual stimuli, in the main to verbal responses, and these serve to facilitate discrimination (e.g., Reese, 1961)

With respect to this last assertion, it is well to pause at this point for brief comment that is relevant to other similar assertions that follow The general explanatory notion that will be reiterated in connection with age-related improvements in learning and conceptual behaviors is that children engage more and more in mental manipulations, elaborations, and even reductions of the materials presented for learning or problem-solving The evidence that children do, in fact, engage in such processing will always remain indirect barring discovery of a direct method for revealing covert events What can be directly established is that acts presumed to occur covertly facilitate, or, in some cases interfere with, performance when they are made overt This characteristic of the argument about processes underlying the present forms of cognitive development has an interesting consequence Research aimed at assessing the facilitating or interfering effects of externally imposed conditions of learning or problem-solving can simultaneously provide evidence relevant to questions on the nature of processes that underlie naturally occurring performance changes Thus the issue of augmenting learning and conceptual competencies is intimately related to the issue of the determinants of the development of such competencies (see Rohwer, 1967, in press)

The signal work of the Kendlers (Kendler and D'Amato, 1955, Kendler, and Kendler, 1961, 1962, Kendler and Mayzner, 1956, Kendler, 1960, 1963, Kendler and Kendler, 1959, Kendler, Kendler, and Wells, 1960) on reversal shift behavior in young children, ages 4 to 10, has led to the hypothesis that children increasingly respond to stimuli with verbal labels that identify one or another or several of their properties Although the final interpretation of observed age changes in

the ease of making reversal shifts (see House and Zeaman, 1962) is in considerable doubt, the Kendlers (1961) have provided evidence that verbalization can either facilitate or interfere with reversal shift performance depending upon whether the verbalization is relevant or irrelevant

Both serial and PA task performance can be facilitated in children by inducing them to use relevant verbalizations. Levin and Rohwer (1968) have shown that the learning of a serial list of nouns by fourth- and fifth-grade children is advanced by presenting the nouns in the context of a single, rather long sentence. Jensen and Rohwer (1965) found that PA learning efficiency is increased in second-, fourth-, and sixth-grade children by the instruction to formulate a sentence containing the two nouns of each pair. Kindergarten children seemed to derive no benefit from this instruction, but in a later study Rohwer and Lynch (1968) showed that sentences provided by the experimenter can facilitate PA learning in children as young as kindergarten age.

Verbal elaboration is not the only method whereby PA learning can be made more efficient. Reese (1965) observed that PAs presented to children 3 to 5 years of age in the form of line drawings depicting some interaction of the two items in each pair (e.g., a picture of a CAT carrying an UMBRELLA) improved performance relative to a condition where the two items were presented separately. In a similar study, Rohwer, Lynch, Levin and Suzuki (1967) showed that pictorially represented interactions among PA items facilitated learning in first-, third-, and sixth-grade Ss. Furthermore, it has been shown that third- and sixth-grade children learn PAs more rapidly when they are presented in the form of pictures than when presented as printed words (Rohwer, Lynch, Levin and Suzuki, 1967). In sum, these results are consistent with the assertion that when children augment the materials presented for learning by elaborating verbal or imaginal structures containing those materials, then performance is facilitated. The next step in the argument is to say that the propensity for engaging in these kinds of elaboration increases with age.

At this point it is appropriate to note that results such as those just reviewed have two

kinds of implication for education. First, they suggest that conditions under which materials are presented for school learning determine the ease with which mastery will be attained. At least with regard to the forms of school learning that conform to the paradigms of discrimination learning, serial learning, and PA learning, it seems clear that an informed and selective use of pictorial representations and verbal labels and contexts will result in more efficient performance. Second, the results suggest that some school time could be used profitably, especially during the kindergarten and even the pre-kindergarten years, to induce habits of elaboration in children so that when confronted with unelaborated materials, as is so frequently the case in schooling, these tactics for learning can be voluntarily brought to bear. Clearly, however, there is a major limitation on the results of these studies insofar as their educational relevance is concerned: the extent to which the conclusions generalize to the learning of school subjects is entirely unknown. Additional evaluation of the effects of these variables must be conducted using materials that are like, if not identical with those used in education.

With regard to problem-solving processes and other forms of learning that are more conceptual than those mentioned thus far, it again appears to be the case that increasing competence arises from increased use of underlying elaborative and analytical processes. Roughly speaking, an account of the increased ability of the child to handle problems in conservation, classification, and transitivity depends upon the emergence, in Piaget's terms, of concrete operations of thought including the property of reversibility. There remains considerable doubt as to whether or not language or verbalization plays anything like a central role in the acquisition of these capabilities. The performances themselves, however, clearly demand that the child engage in mental manipulations, whatever their character. Following the same inference strategy used in connection with improved learning performances, we may ask: What are the conditions under which conservation and reversibility are and are not observed? Assume now that we are speaking of children who do not display these capabilities at the beginning of training. The problem is to explain how chil-

dien who do evince the capacity for conservation and reversibility come to be able to do so

A considerable quantity of research has been reported relevant to these issues and the results have been contradictory. The contradictions in part stem from differences in methodology of investigation (Braine and Shanks, 1965, Davies, 1965) and from differences in definitions of the capability being assessed (Elkind, 1967b). But other contradictions apparently have to do with the educationally relevant matter of the method of training used to facilitate acquisition of the concepts in question. For example, in an experiment comparing two methods of training for number conservation, Wallach, Wall, and Anderson (1967) found training in reversibility to be effective and training in addition and subtraction of relevant objects to be ineffective. Again, a variety of procedures used with the intent of facilitating the acquisition of conservation (Smedslund, 1962, 1961a, 1961b, Wohlwill, 1960, Wohlwill and Lowe, 1962) have failed to produce considerable differences between trained and control children, whereas other procedures that involve masking the results of transformations of materials from the view of Ss (see the discussion of the Frank experiment in Bruner, Olver, and Greenfield, 1966) seem to be successful.

Clearly, the conditions under which numeric and scientific concepts of the sort that appear with great frequency in the work of Piaget and of those who are concerned to validate and extend his findings are of special significance for education. It is equally clear that with regard to instructional implications, there are large gaps in the information presently available with regard to two major questions. The first is whether or not it is possible, and, if so, profitable to facilitate the early emergence of capabilities in children. Piaget apparently thinks that the answer is no (Elkind, 1967a). The second question concerns the possibility of designing instruction so that whatever needs to be taught to children can be presented without requiring unattained capabilities for its acquisition. If this is to be the focal educational strategy, then accurate and reliable means for assessing children's presenting status are an absolute necessity. This brings us to a discussion of

individual differences and of means for assessing them.

Individual Differences Individual differences in learning and in conceptual behaviors is a bifurcated topic. The assessment of individual differences in conceptual attainments has long been a major effort of psychologists and therefore has a long tradition yielding considerable amounts of data. These data pertain, as we noted at the beginning of the chapter, largely to performance on standard, well-known tests of intelligence. We need not review here the present status of knowledge on these kinds of individual differences as traditionally conceived. Rather, we shall take note of recent developments related to the matters of learning and conceptual behavior just reviewed and related as well to the more traditional conceptions of intelligence.

That there is a need for more kinds of assessment than those provided by the traditional intelligence test is amply testified to by recent theoretical formulations emphasizing the need for positing at least two rather different kinds of intellectual processing in children. The position was explicated at some length by White (1965) in connection with a wide variety of experimental data concerning age changes in performance on a number of different learning and conceptual tasks. The second view that we shall mention was prompted in large measure by another body of evidence, one that contains an internal contradiction, namely, the data showing SES and ethnic differences in intelligence but not in learning efficiency (Jensen, 1969).

White (1965) distinguishes a lower level (associative) and a higher level (cognitive) of mental processes. He marshalls considerable, strikingly varied sources of evidence to the effect that a shift from the dominance of the associative to that of the cognitive processes occurs in the age range of 5 to 7 years. The shift is summarized in terms of four general transitions: (1) from direct responses to available stimuli to responses produced by mediated stimuli, (2) the emergence of the capability of inducing invariants in the face of phenomenal variability, (3) the capacity for organizing past experience to allow inference and prediction, (4) increased sensitivity to information yielded by distance as

against near receptors. Obviously, each one of these relatively general changes from lower- to higher-level mental processes is capable of translation into a number of measurable variables, each of which may yield reliable individual differences. Given the developmental nature of the theory, the most interesting kind of individual differences would be those that might emerge as a result of interactions between subject variables, task variables, and age. Thus, for example, one might expect to find that males and females cross the various transitions at different chronological ages or that within one of the four transitions, males would be found superior to females and within another the reverse would be the case.

It is precisely because of observed interactions of this kind that Jensen (1969) has promulgated a similar version of a two-process theory of learning abilities. This version, like White's, posits a lower-level, associative ability and a higher-level, cognitive ability. The lower-level ability is illustrated in terms of the kinds of capability necessary for adequate performance on a task such as that of the simple digit span. The higher-level ability is exemplified in terms of the kinds of processing required by a task such as that of solving the Raven Progressive Matrices problems.

The two-process theory is especially potent with regard to some interesting data that are beginning to be reported regarding SES- and ethnic-related differences in performance on learning and conceptual tasks. It has been shown, for example, that low- and high-strata children of elementary-school age perform equally well on tests of serial learning (Rapier, 1968), PA learning (Rapier, 1968, Rohwer, Lynch, Suzuki, and Levin, 1968), and digit-span (Jensen, 1969). Children drawn from these same populations, however, have repeatedly been found to differ markedly on tests of intelligence (see, e.g., data reported in Deutsch and Associates, 1967, Rohwer, 1967, 1968). These two kinds of data are consistent with an interpretation in terms of two levels of learning ability. The conception is that low- and high-SES children differ in cognitive abilities but not in associative learning abilities.

The data relevant to the issue are by no means complete and an attempt to furnish more adequate evidence is presently underway (Jensen and Rohwer, 1966, Rohwer

1968). Even at this point, however, the issue is not quite as clear as described thus far. The complication is an interesting one, for it involves a developmental factor. It has been shown that SES differences in learning ability can be detected at early age levels (3 to 5 years) on the same kind of PA task that yields SES equivalence at later ages; the task is sufficiently difficult that a ceiling-effect interpretation cannot be made (Rohwer, 1967, also see Semler and Iscoe, 1963, for a parallel effect with respect to Negro-White comparisons). When the necessary data are obtained, similar convergence may be found for other tasks as well. The important question to be answered by such data is whether or not convergence with age of SES groups obtains for both lower- and higher-level learning abilities or just for the lower-level abilities.

The answer to this question is critical for educational practice. Suppose that Jensen's two-process theory is valid, that is, suppose that substantial numbers of low-SES children are characterized by an enduring deficit in higher-level, cognitive abilities. Also suppose, as Jensen (1969) has suggested, that SES differences in cognitive abilities are largely attributable to genotypic differences between populations. The implication that follows from these suppositions is that instruction must be designed in very different ways for children from upper- and lower-SES populations. For example, if a curriculum were designed for low-SES children, it could not be assumed that the children were capable of self-initiated cognitive activity of the sort needed for the induction of rules from examples. If induction were a necessary component of the subject matter to be learned, it would have to be taught explicitly. In contrast, suppose that variance between upper- and lower-SES children in cognitive level abilities is principally attributable to environmental rather than to genetic variation. In this case the implication is that systematic attempts would be needed to explicitly induce low-SES children to acquire the use of cognitive skills. Presumably, such an attempt would not be particularly successful if it were prosecuted by means of enrichment methods since these are predicated upon the child's possession of inferential cognitive abilities. Instead, the indication is that the conditions for acquiring

cognitive skills should be designed to permit the low-SES child to use maximally his associative learning abilities

On the other hand, suppose that a developmental interpretation of SES differences in associative and cognitive abilities is valid, that is, suppose that with respect to both kinds of learning the abilities of lower- and higher-SES children converge with increasing age so that the convergence of associative abilities occurs at earlier ages than that of cognitive abilities. This supposition suggests two alternative educational strategies. The first assumes that these developmental differences are maturationally determined and simply involves scheduling instruction at later ages for lower- than for higher-SES children. The low-SES child, for example, might not enter kindergarten until age 7 rather than at age 5. Alternatively, SES differences in developmental rate might be assumed to be environmentally determined and therefore susceptible to change through the implementation of specially prepared preschool curricula. This, of course, is the assumption that underlies current efforts such as Project Headstart. Note, however, that the developmental interpretation implies the selection of preschool curricula that involve explicit instruction in the acquisition and use of cognitive skills. The enrichment approach common in many middle-class nursery schools is contraindicated for low-SES children since many of the cognitive skills necessary for the success of such a program are precisely the ones that must be fostered. Instead, the approach should provide for the acquisition of cognitive skills by means of available associative processes.

Most impressive data relevant to these educational implications have been reported by Lesser (Stodolsky and Lesser, 1967, Lesser, Fifer, and Clark, 1965). Specially designed tests of mental abilities (Verbal, Reasoning, Number, and Space) were administered according to a balanced design to samples of first-grade children drawn from each of the eight populations defined by the factorial combination of two variables, social class (middle versus lower) and ethnicity (Chinese versus Jews versus Negroes versus Puerto Ricans). The results were clear and striking. Within every ethnic group, there was a substantial effect associated with social-class membership such that middle-class chil-

dren performed significantly better on each of the four subtests than lower-class children. But the pattern of performance across the ethnic groups was relatively independent of social-class and quite distinctive for each ethnic group. As Fig 1 reveals, the pattern of performance within an ethnic group was virtually the same for both social-class groups but the pattern for one ethnic group differed markedly from that of the others. There were also differences among the various groups with respect to absolute levels of performance on the four subtests, but for the present issue the important result was that marked individual differences associated with ethnic group membership emerged for the mental abilities assessed. These findings are the more impressive because they have been replicated on two entirely independent samples (Stodolsky and Lesser, 1967).

What conclusions and implications for educational practice are to be drawn from these data? It is clear the implications are not simple ones. As Stodolsky and Lesser (1967) argue so persuasively, the goal of identical educational development for all children must give way to the goal of maximal educational development for all children. The most important implication is that psychologists of

Fig 1 Patterns of normalized mental-ability scores for middle- and lower-class Chinese children

Fig 2 Patterns of normalized mental-ability scores for middle- and lower-class Jewish children

cognitive development and educators alike must face up to and begin to make provisions for individual differences. As Hirsch (1967) has so vigorously emphasized, variability among individuals is the basic fact of behavior, it must guide our efforts at educational design and our attempts to enhance educational development.

Finally, with respect to individual differences in learning and conceptual behavior, it should be clear that research must continue to be designed to reveal the sources and the patterns of variation among children. It must be repeated that research of the kind reported by Stodolsky and Lesser (1967), by Jensen (1969) and by Rohwer (1967, 1968) urgently needs to be carried out developmentally, that is, across an age range that at least matches that spanned by the elementary school years. It is important to know, for example, whether or not the ethnic differences in patterns of mental ability reported by Stodolsky and Lesser (1967) for first-grade children endure throughout the educational life-span. Without such information it is impossible for curriculum designers to know at

what points it is necessary to provide for such individual differences in order to facilitate educational development.

Augmenting Learning and Conceptual Competencies We have already noted some procedures that are promising for facilitating the acquisition of specific forms of learning and conceptual competencies as, for instance, in the case of the verbal and visual elaboration of learning materials (Rohwer, 1967, Milgram, 1967) and in the case of reversibility (Wallach, Wall, and Anderson, 1967). There remain developments in five other areas that have more general application to the problem of facilitating educational development. These are discovery methods, programmed instruction, computer-assisted instruction, detailed operant techniques for remediation, and pre-school programs. Each of these areas of application has such direct implications for educational practice and is so thoroughly discussed elsewhere that they will be mentioned here only in summary form.

The approach to instruction known as the discovery method has acquired great fashion among some psychologists and among many educators. Many of the new curriculum efforts, in fact, are built largely upon the assumption that learning by discovery has the advantage over the alternatives (see, e.g., Suchman, 1960, 1961, Davis, 1966). The advantages of the discovery method are presumed to be increased motivation, better retention, and wider transfer rather than more efficient initial mastery of presented materials.

Let us consider, for example, the method of inquiry training developed by Suchman (1960). This method has been applied principally to elementary science instruction and is designed for use in groups of about 10 students each. A typical training session begins with the presentation of a silent motion picture depicting some physical event such as the collapse of an empty sealed varnish can with cooling. The students' task is to discover an explanation for the event by asking questions in a form that the teacher can answer either "Yes" or "No." For example, the teacher will answer a question like "Was the can at room temperature to begin with?" but will not answer one like "Why did the can collapse?" Thus the teacher is a source of information but not a source of strategies for gaining information. The intent of the

method is for children to learn to frame questions so as to obtain unequivocal information, to sequence the questions so as to establish early in the session the information prerequisite for further progress, and to draw inferences from the information obtained in order to evaluate hypothetical explanations of the event observed. At the end of each inquiry session, a critique period follows in which the children and the teacher discuss the tactics and strategies of inquiry in order to improve the students' competence in the use of the method. Suchman (1960) reports that after 15 1-hour sessions of this kind

Most of the children who receive training become more productive in their design and use of verification and experimentation. They develop a fairly consistent strategy which they can transfer to new problem situations. They make fewer untested assumptions, they formulate and test more hypotheses, and they perform more controlled vs uncontrolled experiments in the course of their inquiry (Suchman, 1960, p. 47).

Critical reviews of the literature on discovery methods have appeared (Ausubel, 1961; Gagné, 1966b; Wittrock, 1966) and reveal that, as yet, we have very little systematic evidence about the effects of discovery methods on motivation, retention, and transfer. Evidence that has been collected seems to indicate that unguided discovery is inferior on all measured counts to procedures of guided discovery (Kersh, 1958).

Gagné and Brown (1961), for example, have reported the results of an experiment in which the terminal task presented to ninth- and tenth-grade subjects was that of finding a formula for obtaining the sum of four different kinds of number series. The subjects were divided into three groups according to the kind of pretraining administered. The first kind, Rule and Example, consisted of an expository learning program in which a rule for finding the sum of a particular kind of number series was presented followed by appropriate examples of such series. The second kind of pretraining, Discovery, involved the presentation of a number series with the instruction to find a formula for obtaining the sum of such a series. A series of successive hints was available for presenta-

tion as subjects indicated a need for them in order to solve the problem but at no time was the answer provided. The Guided Discovery program, the third kind of pretraining, contained a series of items for each type of series. The items asked questions relevant to the formula to be obtained and offered multiple choice answers to the questions. The sequence of items was designed to lead the subjects systematically through the information needed to obtain the required formula. In terms of performance on the terminal task, the Guided Discovery group was best, followed by the Discovery and Rule and Example groups, in that order.

Perhaps the most important thing to be said about discovery learning and education at this point is to echo the positions taken by Cronbach (1966) and Kagan (1966): research is needed to establish the specific advantages and disadvantages of identified discovery methods for particular contents to be learned, objectives to be attained, and for specific kinds of learners who are to be instructed. For additional discussion of the topic, the reader is referred to Shulman and Keislar (1966).

Just as discovery methods have enjoyed a certain fashion among educators, so have methods of programmed instruction. Unlike the case of discovery, the topic of programmed instruction is replete with experimental studies of the effects on learning outcomes of component factors such as step size, mode of response, type, frequency and mode of feedback, and sequencing (see Lumsdaine, 1964, for a review). From a currently dominant viewpoint, the educational importance of programmed instruction is not so much that it provides a discrete set of techniques for instruction but that it concretely illustrates the possibility of predesigning instructional materials (see Lange, 1967). Research on programming, then, is useful insofar as it sheds light on the variables that contribute to the success or failure of attempts to map out instructional sequences that are relatively independent of teacher decisions. The argument is a simple one. Teaching virtuosity is and in all probability will continue to be rare and the teacher has much too much to manage already without the burden of making minute-by-minute curricular decisions. The practice

of leaving the success of schooling to the teacher cannot be warranted any longer.

To take an example, the line of research reported by Rothkopf (Rothkopf, 1965, 1966, Rothkopf and Coke, 1963, 1966, Rothkopf and Bisbicos, 1967) has considerable relevance for the task of predesigning instruction, even though it is not advertised much as research on programmed instruction. Rothkopf has shown, for instance, that the incorporation of certain kinds of testlike questions within sequences of written material can facilitate learning from such materials. The types of questions asked and the placement of the questions have been shown to affect the success of the method. Moreover, it has been shown that testlike questions can have effects that interfere with performance as well as effects that enhance performance. Developmental studies of these effects on learning are needed to support the investigations already reported, especially insofar as they can extend the age range of the populations sampled down into the elementary-school level. According to Rothkopf (Rothkopf and Bisbicos, 1967) the effect of questions placed immediately after the relevant segments of written material is to increase inspection behaviors on the part of students. Although he is pessimistic about the possibility of installing such behaviors as enduring habits, this potential is worth considerable assessment in its own right.

All of the remarks made thus far about programmed instruction and the predesign of educational materials apply equally to the topic of computer-assisted instruction (CAI). The role of the computer in CAI is manifold. Consider, for example, the system in use at Stanford University in connection with first-grade reading instruction (Atkinson, 1968). Each of 16 children is seated at an individual terminal equipped with presentation devices (projection screen, cathode ray tube, and earphones) and response devices (typewriter keyboard and light pen). A program of instruction is predesigned and stored in the computer which selects items for presentation to the child depending upon his previous record of performance on an initial screening test and on the test items contained within each frame of the program. Materials can be presented on any one or a combination of the display devices in connection with a given frame of

instruction. If a child's answer to the question contained within a frame is correct, he is presented with the next frame in the main line of the program. If his answer is incorrect he is presented with the initial frame of an appropriate remedial loop. The child's response with either the light pen or the typewriter input provides the information necessary for the computer to choose between these alternatives. The response is also sufficient to permit the computer to display to the child informative feedback as to whether or not his response was correct. Finally, the system is designed to record automatically the child's performance, providing a history of his progress through the instructional program. At the end of the first year the CAI program was evaluated. The performance of the CAI group on standard tests of reading achievement surpassed that of a comparable control group that had been provided with customary first-grade instruction in reading.

An additional comment must be made about a distinctive feature of computer-assisted instruction precisely because of its signal importance for education. As Suppes (1964) has indicated, the enormous magnitude of individual variation in learning is revealed most clearly by methods of instruction, such as computer-assisted methods, that provide for the accommodation of these differences. The individualization of instruction has been a positively valued goal in American education for many years. But literal provision for individual differences has been minimal for very good reasons, including (1) the extent of individual variation has only been suspected and not dramatically or empirically known, and (2) providing for individual variation is an arduous and perhaps even an impossible task without technological aid, especially given the dominance of classroom modes of organization in the schools. The use of computer methods in education will, hopefully, remove the possibility of ignoring in practice the necessity of individualizing instruction.

Our concern with individual variation has thus far taken us only part of the way out toward the tails of frequency distributions of children's performance on educational tasks. What of children who seem irredeemably fated to fail in school? Recent work informed by a rather strict commitment to the

tenets of operant and classical conditioning shows some promise of remediating seemingly irreversible deficits. The work of Lovaas (Lovaas, Freitag, Gold, and Kassorla, 1965; Lovaas, Schaeffer, and Simmons, 1965), although still quite controversial, is impressive for its attempt to modify seemingly intractable behaviors in autistic children. Less bizarre behaviors such as pervasive reading deficiencies have been shown to yield to intervention using operant techniques (Staats and Butterfield, 1965). The characteristic specificity of the operant approach to learning is clearly evident in this effort and apart from its apparent success as a remediation technique, the approach can contribute to educational practice if it succeeds in impressing schoolmen with the fact that learning is a complex undertaking composed of almost innumerable specific acquisitions that are prerequisite to any further progress.

Finally, mention must be made of a very different educational strategy designed to ameliorate individual differences, namely, the burgeoning interest and implementation of programs in preschool education. All manner of such programs are presently in operation, from the sort predicated on the value of traditional nursery school enrichment to those that lean heavily on the presumed efficacy of early training in academic skills. In other connections we have already mentioned the programs under the direction of Deutsch et al (1967), Gray (1966), and Bereiter and Engelmann (1966). The last of these is notable for its rigid adherence to an academic model of preschool education in marked contrast to the customary nursery school enrichment model. Bereiter and Engelmann (1966) set forth 15 academic objectives as the minimal goals of a preschool education program. These objectives are specific and stated in behavioral terms as illustrated by the following selections:

Ability to use the following prepositions correctly in statements describing arrangements of objects: on, in, under, over, between. "Where is the pencil?" "The pencil is under the book."

Ability to perform simple *if-then* deductions. The child is presented a diagram containing big squares and little squares. All the big squares are red, but the little squares are

of various other colors. "If the square is big, what do you know about it?" "It's red."

Ability to name the basic colors, plus white, black and brown.

Ability to count aloud to 20 without help and to 100 with help at decade points (30, 40, etc.).

A sight-reading vocabulary of at least four words in addition to proper names, with evidence that the printed word has the same meaning for them as the corresponding spoken word. "What word is this?" "Cat." "Is this a thing that goes 'Woof-woof?'" "No, it goes 'Meow'." (Bereiter and Engelmann, 1966, pp. 48-49)

The program of instruction instituted to achieve these objectives may be characterized as one of specific, direct teaching. If the objective is the capability of counting objects correctly up to 10, the children are given highly repetitious practice in counting objects up to 10. It is interesting to note that the instructional practices described by Bereiter and Engelmann conform closely with principles of simple, associative learning. The two principles most in evidence throughout are repeated practice of correct responses and reinforcement for correct responses.

The instructional program is designed to fit within a 5-day-a-week, 2-hour-a-day schedule. One hour each day is devoted to intensive teaching and learning directed toward the attainment of the program's objectives. This hour is distributed in three 20-minute segments separated by periods of less structured activity. The three segments are devoted to instruction in language, arithmetic, and reading skills. A different teacher is responsible for each of the three subject-matter areas so that the children are in the charge of three individual teachers.

The results of a preliminary assessment of the Bereiter-Engelmann preschool program suggest that it is a promising method for increasing the rate of educational development in culturally disadvantaged children. Fifteen low-SES children were enrolled in the program for a 9-month period. The average age of the group at the outset was 4½ years and the average IQ was 93. At the end of the period, the average IQ had risen to 100. Moreover, the average performance of the sample on the reading and arithmetic

subtests of the Wide-Range Achievement Test was advanced a full year beyond age level. The conclusions that can be drawn from these results are limited by the fact that appropriate control groups were not selected for purposes of comparison.

Massive programs like Project Headstart and related governmental efforts have also been subjected to evaluation (Williams and Stewart, 1966, Boyd, 1966, Temp and Anderson, 1966), but their characteristic inattention to design for evaluation makes it difficult to draw compelling conclusions. That is to say, unless such efforts are planned with evaluation in mind, the amount of information yielded cannot be maximal. In an effort as large and as unsystematically varied as Project Headstart little can be discovered about the relative effectiveness of specific variants of preschool education. At a time when the mood in education and in public agencies responsible for education strongly favors the institution of pre-kindergarten schooling as a matter of routine, it is crucial that hard information be made available about the effects of such practices.

A model piece of research in this regard has recently been reported by Leniow (1967). The study contrasted the effectiveness of three different preschool programs for assisting children to achieve increased competence in both convergent and divergent modes of thinking and problem-solving. Provision for assessing the effects of the programs on these behaviors was made quite intentionally and no effort was spared to institute the best possible version of each of the kinds of program studied. Apart from demonstrating the advantages of a convergent training or direct teaching program for performance on tests of logical thinking and that such a program had no deleterious effects on divergent thinking abilities the study revealed once again the pervasiveness of individual differences, not only in presenting status but in response to intervention. It was found, for example, that a number of the children given convergent training showed a greater propensity for exploratory activity than children given divergent training, whereas other children given the convergent training showed considerably less. Clearly, these results are not, by themselves, of enormous significance. Both longer-term programs and longer-term effects

of such programs need similar evaluation, more attention should be given to the number and variety of dependent measures to be used in indexing the effects of such programs. Nevertheless, Leniow's effort is remarkable for the care taken to plan for evaluation and the attention given to the possibility that multiple consequences, some of which could be contradictory, might result from a single type of preschool education.

SUMMARY, SPECULATION, AND IMPLICATIONS

Let us conclude by reiterating some of the themes that have appeared and reappeared in these pages. It is important as well to characterize what the reader has been offered here in the name of implications of cognitive development for education. For the present treatment has by no means exhausted all of what the psychology of cognitive development has to offer to education. Intentionally, greater emphasis has been given to what schoolmen need from the scientific study of cognitive development than to what they can now obtain from it. This choice was made in the belief that the current status of theory and research as it relates directly to educational practice is very preliminary indeed. The purpose was to underline the kinds of research that are desperately needed if education is to be improved. The need is desperate because education is presently changing and the changes are, in many cases, being made without recourse to evidence that the direction is favorable for the children who will be involved—thus the recurrent themes.

Two kinds of research are necessary if the psychology of cognitive development is to contribute to educational change. The first is basic research, which starts with psychological phenomena that reveal themselves in schooling, such as the phenomena associated with learning to read. For a developmental psychologist to engage in such research, he must change only his strategy for choosing researchable phenomena. After the choice, the method is that of experimental analysis and, with luck, the results are of both practical and theoretical significance. The second kind of research is ancillary to the first but of equal importance if the first is ever to contribute to educational change. This kind of

research involves the psychologist with subject-matter and curriculum specialists in evolving, evaluating, and modifying instructional programs and materials. An emphasis on this kind of research belies an underlying skepticism about the direct applicability of the results of basic research in the schools. Hence, the typical pattern will probably involve modifications as the translation to practice is attempted.

The present character of research in the general area bounded by education, psychology, and cognitive development is that educational research is too infrequently developmental and research in cognitive development too infrequently begins with phenomena that arise in schooling. Despite this, there are hopeful signs. Theoretically, the recent formulations by Bruner and by Gagné indicate a commitment to work toward the satisfaction of the educational needs we have reviewed. Both formulations incorporate attention to phenomena germane to schooling along with a developmental view of the educational process. With regard to research, the various efforts that have come under the umbrella of Project Literacy, for example, promise to result in both evidence and materials that can contribute to educational change. In general, the trend, if one can be perceived, seems to be toward a growing relevance of research and theory in cognitive development for educational problems and toward a growing use of this resource by schoolmen.

A second major theme of the chapter has been the contention that special attention to individual differences is crucial for the success of any enterprises aimed at promoting educational development. It is variability after all that forms the starting point of psychological research, and one of the most legitimate and important aims of such research is surely isolating and describing the sources and determinants of individual differences. There are several topics embedded here. One concerns the development of means for measuring individual differences, for classifying them, and for reliably identifying individuals who belong to the various classes. Another concerns the specification of the measures that are necessary for determining the presenting status of students at any important educational juncture. Still another matter that awaits clarification is the extent

to which individual differences detected at one developmental level persist to and through other levels. Finally, it remains to determine which of the individual differences detected are amenable to modification and which will simply have to be provided for by distinctly different forms of educational practice.

Related to all of these issues of individual variation is the enormous task of designing instruction to be responsive to them. The problems here are not easy to solve. We do not know what learning conditions are most facilitative for impulsive as compared with reflective children, for Chinese as compared with Negro children. But even given this kind of knowledge, we will still be faced with the task of detecting and providing for individual differences in the response of such groups to the instructional programs designed for them.

It is not yet clear how the commanding need for individualization of instruction is to be met. It seems certain that the conception of the classroom must give way to that of the student as the basic unit of educational organization. Indeed, it might be the better strategy to induce schools to shift in the direction of psychological experimentation than to expend effort in determining how to maximize the effectiveness of present school practices. That is to say, for manifesting what and how much an individual has learned, the individually administered task has a distinct advantage over classroom recitation. But such a recommendation cannot be made until we have provided educators with effective means for assessing students and then progress all along the interval of life devoted to formal education, and with respect to the kinds of learnings and development the schools seek to engender. Not that these objectives must be accepted as is. Changes here are probably warranted as well, but until we can provide adequate methods for assessing more than measures of PA learning efficiency or the propensity for making reversal shifts, our suggestions must remain limited. Make no mistake, the capability for making such assessments is important as well, for it is clearly necessary to identify a diverse array of competencies in children including various kinds of learning abilities as well as more general collections of abilities such as intelligence and creativity.

The final theme that deserves emphasis in

closing is the need for explicit, behavioral statements of educational objectives. At a time when an increase in the number of years to be devoted to formal schooling is seriously planned, it is nearly unconscionable to do so for vague and general purposes regardless of the humanitarian and altruistic character of the rhetoric used to describe them. It may require a considerable sacrifice of illusions

about educational objectives, but until we demand to know specifically how we can tell a successful education when we see one, we may never be able to help in producing one. Nor can we assist in solving one of the great and continuing problems of instruction—revealing to the instructor whether or not a student has learned whatever it is he was intended to learn.

Zubin, J , 635, 646, 651

Zuntz, N , 483, 502, 544, 563

Zwart, 722, 732

Zweizig, H , 210, 280

Subject Index

- Abdominal reflex, in fetus, 510
- Abnormal psychology, 657
- Abortion(s), chromosomal abnormalities in spontaneous, 451
- Abstraction, language acquisition and problem of, 1086f
- Abstractness-concreteness, 1286, 1288, *see also* Integration, complexity of
- Abstract relations as a transformation of concrete perceptual relations, 737
- Academic achievement, and creativity, 1220ff
- Acceleration in physical growth, 77f, 99f
 - as trend, 145, 147
- Accommodation(s), 327, 707ff, 714, 792, 968
 - and assimilation, equilibrium between, 708f
 - visual, 777
- Acetylcholine, 461, 490
- Achilles tendon reflex, fetal, 512f
- Acidosis, in fetus, 227ff
- Acquired distinctiveness of cures, 1428
- Acquired equivalence, 820
- Acting, assimilation as a means of, 738f
 - practical judgment as a means of, 739
 - reflex, 738
- Action, primitive, 751
- Action patterns, fixed, *see* Fixed action patterns
- Action-specific energy, 7, 10, 12, 23, *see also* Fixed action patterns, Innate behavior
- Activity, as measurement of behavior in infants, 297
 - fetal, 296
 - heredity and, 55f
 - interpretation of, 320f
 - in neonate, 294, 339
 - schematizing, 742
 - significance of, in infant, 296f
- Adaptability to changing environment, 625f
- Adaptation, 677, 684, 690, 709, 736
 - cognitive, 708
 - to environment, 625f, 703
 - of intelligence, 703
- Adaptation mechanisms for behavior, 6
- Adaptive behavior, 449, 672, 689
 - adaptive change, 733
 - adaptive flexibility and divergent thinking, 1214ff
- Adaptive flexibility factor, Guilford's, 1327
- Adaptive intentions, and cognitive controls and styles, 1277
- Additive genetic variance, 49
- Adduction, contralateral limb, 510
- Adolescence, 78
 - athletic ability and, 96
 - changes in body composition at, 94f
 - endocrine glands and, 115
 - growth and development, at, 93ff
 - hemoglobin at, and sex differences, 96
 - "outgrowing strength" and, 96
 - sterility in, 99
 - voice-breaking and, 98
- Adolescent growth spurt, 78f, 93ff
 - adrenal androgens and, 117f
 - age and peak velocity of, 83, 94
 - bone growth and, 94f
 - earlier growth and, 94
 - fat growth and, 94f
 - heart rate and, 212
 - muscle development and, 94f
 - reproductive organs and, 84f
- Adolescent sterility, 99
- Adopted children, studies of, 605
- Adrenal androgens, adolescent growth spurt and, 117f
- Adrenal ascorbic acid in fetus, 580
- Adrenalectomy of pregnant rats, 580
- Adrenal gland, 113f
- Adrenal hypertrophy, fetal, 580
- Adrenarche, premature, 117
- Adrenarche hormone, 117
- Adrenocortical hormones, 117
- Adrenocorticotrophic hormone (ACTH), 112, 116f
- Advanced Research Project Agency, 1061
- Aesthesiometer, 794
- Affect, development of, 316f
- Affectional systems, 596
 - in monkeys, 602ff
 - in primates, 599
- Afterbirth, 468
- Age, 576, 632
 - and associative flow, 1252ff
 - behavioral, 452
 - blood pressure and, 203
 - chronological, 1167
 - conception, 495
 - concept learning and, 899ff
 - copulation, 495
 - developmental, *see* Developmental age
 - eidetic imagery and, 818
 - estimation of human gestational, 497
 - fertilization, 495
 - and field dependence, 807f
 - and incentive effects in probability learning, 897
 - and incidental learning, 909ff
 - insemination, 495
 - mean menstruation, 496
 - mean utterance length as a function of, 1104t
 - menstruation, 496
 - mental, 452, 1167
 - oddity learning and, 881
 - ovulation, 495
 - and peak velocity of adolescent growth spurt, 83, 94
 - and perceptual activity, 718
 - probability learning and, 893ff
 - and rate of cognitive development, 713
 - and speed of discrimination, 856
 - stimulus generalization and, 863
- Age differences, antibodies and, 179

- energy metabolism and, 232ff
 Age shifts in learning experiments, 671ff
 Age trends, in respiratory rate, 226ff
 in terminal respiratory units, 217
 Age-zones, 630
 Agglutinogens, 164
 Aggression, 12f, 29f, 676
 in doll play, 676
 imitative, 917
 imprinting and, 465
 interspecific, 12f
 intraspecific, 19
 learning of, 917
 redirected, 12, 29
 Aggressive behavior, 12f, 19, 29ff, 917
 Aggressiveness, heredity and, 55f
 Ahlfeld breathing movements, 448, 501f, 510, 529
 Ahlfeld sign, 501
 Albertus, 460
 Alcohol, ingested by pregnant mother rats, 581
 mother's use of, 586
 Alcohol preference, heredity and, 55f
 Aldosterone, 117
 Aldrovandus, 460
 Alimentation, behavior and, 453
 Allantois, 159ff, 466
 Allele(s), 39
 dominant, 42
 linkage, of, 44
 recessive, 42
Alosa finta, early movements in embryos of, 454
 Altitude, effect of, on pregnancy, 491
 physical growth and, 138
 "Altricial," definition of, 447
 Amaurotic idiocy, 60
 Ambivalent behavior, successive, 12
Amblystoma, see Salamander
 Amebas, 568
 American Association for Advancement of Science, Committee on Grants for Research of the, 659
 American Heart Association Committee on Blood Pressure, 197
 Amino acids in hemoglobin, 165
 Amnion, 159ff, 462, 466, 468, 505
 Amnion contractions in chick, 462f
 Amniotic fluid, 159, 465, 503, 526f
 specific gravity of, 499
 Amphibians, development of behavior in, 455ff
 Analogous functioning, 737, 748
 between stages and systems of action, 737
 Analysis, 961
 as a means of mental activity, 739
 Analytic concepts, 1306ff
 Analytic-global functioning, Witkin's, 1323, 1327, 1329, *see also*
 Field dependence-independence
 Anesthesia, effect of, on fetus and mother, 163
 Androgen-adrenarche, 117
 Androgens, 114
 Androgen-sterilized rat, 115
 Androgyny, discriminant function of, 102
 Androstenedione, 114
 conversion of, to testosterone at puberty, 117
 Anemia, causes of, in newborn, 169f
 erythropoietin and, 165
 "physiological," of infancy, 166
 Animal consciousness, psychology of, 657
 Animal growth curves, *see* Growth curves
 Anoxia, during gestation and labor, 168
 perinatal, 307
 Antecedent-consequent analysis of child-rearing consequences, 675ff
 Anthropometric measurements, choice of, 88f
 decimal age and, 89
 Anthropomorphism, 13f, 20
 Antibodies, and age differences, 179
 in adult, 176ff
 at birth, 178
 in fetus and neonate, 176ff
 life span of circulating, 176
 Anticipatory function, law of, 448
 Anticipatory morphological maturation, law of, 527
 Antigens, reactions of neonate to, 179
 Antitype, 567
 Anxiety, 675, 1303, 1305, 1311, 1314ff, 1350f
 blood-borne, 585
 conditioning and, 860
 fantasy and, 1260ff
 hostility and, 1351
 imprinting and, 465
 and paired-associate learning, 905
 passivity and, 1351
 peer rejection and, 1351
 pregnancy, 585
 sex role and, 1351
 test, 1315f
 Apes and monkeys, growth curves of, 87
 Aphasics, 740
 Appetitional conditioning, 852f
 Appetitive behavior(s), 9f
 characteristics of, 9
 compared with consummatory act, 9
 intention movements in, 9
 moods (readiness to act) and, 9ff, 23
 vacuum activity in, 10
 Applied-basic distinction, 679
 Approximation, successive, 955f
 Area conservation concept, 1018
 Army Alpha and Beta tests, 1170
 Army, Department of the, 1381, 1447
 Arousal, state of, 320, 329, 339, 341
 Arousal level, sucking and, 338
 Arterial wall thickness in fetus and newborn, 189
 Arteries, embryonic, 159ff
 omphalomesenteric, 159
 umbilical, 159ff
 vitelline, 159
 Articulation, cognitive complexity and, 1280
 Articulation theory of speech perception and discrimination, 1428
 Ascorbic acid, adrenal, in fetus, 580
 Asphyxiation in newborn, 185
 epilepsy and, 502
 Assimilation, 327, 741, 754, 968
 and accommodation, equilibrium between, 708f
 biological, 707
 in cognitive development, 706ff, 714
 general concept of, 707
 Assimilations, generating of, 706ff
 genetic, 707
 Associates test, attention deployment in, 1244ff
 Associational fluency, and divergent thinking, 1213ff
 Associationism, 686f, 708
 Associations, development and, 706, 708
 synthesis of learned, 963ff
 Associative flow, playfulness and, 1250ff
 Associative fluency, uniqueness and, 1240ff
 Associative (lower level) mental processes, 1436
 Associative processes, creativity and, 1240ff
 Associative responding, indecisiveness and, 1242
 Associative response probability, gradient of, 1242ff
 Associative uniqueness, training of, 1241ff
 Assortative mating, 51
 "Atlas" method for assessing skeletal maturity, 104f
 Atmospheric changes, behavioral effects of maternal exposure to, 582
 Atomism in cognitive development, 706
 Attachments, social, *see* Social attachments
 Attention, 328, 334, 339ff, 674, 690, 824ff, 1294, 1298, 1301ff, 1421ff
 augmenting of, 1422f
 complexity preference and, 818f

- controlling of, as an instructional function, 1402
- development of, 818ff
- directed, 1297f
- distraction and, 821
- distribution of, in 4-month-old infants, 1367f
- and effects of vigilance distractors, 1423
- encoding and, 1297f
- focus of, 1298
- during habituation, 1368
- individual differences in, 1422
- in infancy, 1298f
- measurement of, 1298, 1367, 1369, 1373f
- memory and, 1303
- redundancy and, 819
- reinforcement and, 1423
- retinal rivalry and, 822
- selective, 809, 824, 1294, 1297ff
- sex differences and, 1368, 1373f
- stimulus determiners of, 818f
- stimulus preference and, 818ff
- and stimulus-response analysis, 666
- sustained, 1299ff
- Attentional responses, pattern of, 1367f
- Attentional theory, 671
- Attention deployment, in associates test, 1244ff, *see also* Day-dreaming
- Attitudes, IQ and, 1192ff
- Audiogenic seizures, 583
- heredity and susceptibility to, 56
- Audition, in infant, 319, *see also* Hearing
- Auditory discrimination, 856, 879, 1428
- and socioeconomic differences, 1428
- Auditory experience, rats exposed to complex, 592
- Auditory processes, 689
- Auditory sensitivity, 793ff
- Auditory stimulation, effects of early, 592
- Auditory stimuli, 342
- and learning, 856
- Auscultation method for measuring blood pressure, 195
- Autism, 685
- Autistic children, instruction of, 1442
- Autistic patients, improvement in behavior problems of, 683
- Auto-instructional program, 1413
- Automatization factor in cognitive functioning, 1342ff
- Autonomic responses, 1298
- Autoregulation, *see* Self-regulation
- Autosomal anomalies, 46
- Autosomal gene pair, 40
- Autosomal trisomy, 45f
- Autosomes, 44
- Aversive behavior, 9
- Avoidance responses, 590ff
- Awareness, 949ff
- Axillary hair, 103, 118
- time of appearance of, 98
- Babbling, as related to speech, 1130ff
- Babies, colicky and noncolicky, 585
- low-birth-weight, 92
- short-gestation-period, 92
- small-for-dates, 92
- see also* Infant, Neonate, premature babies
- Babinski reflex, 509
- Babkin reflex, 854
- Baby biographies, 299ff, 327
- as source of information, 299ff
- values and limitations of, 299
- Babyishness, 20f
- as a releaser of behavior, 20
- response to, 20
- survival value of, 21
- Bales-Couch Acceptance of Authority (AA) Scale, 1333
- Basophils, 171ff
- Bayley California First-Year Mental Scale, 1178
- Bayley Mental and Motor scales, 1169f
- Bayley-Pinneau tables, 109
- Bayley Scales of Infant Development, 1168, 1170f, 1173
- Bayley's First-Year Mental Scale, 1173
- Behavior, adaptation mechanisms for, 6
- adaptive, 449, 672
- adult, influence of prenatal stress upon, 69
- adultlike, of children, 672
- aggressive, *see* Aggression, Aggressive behavior, and Aggressiveness
